Szarka conducted a study to validate <sup>13</sup>C-Spirulina platensis gastric emptying (GE) breath test (GEBT) with a standardized meal. The study included 38 healthy volunteers and 129 patients with clinically suspected delayed gastric emptying (GE) who underwent measurements at 45, 90, 120, 150, 180, and 240 minutes after a 238 kcal meal labeled test with 100 mg [<sup>13</sup>C]-S platensis and 0.5 mCi <sup>99m</sup>Tc. The authors established normal ranges for scintigraphy with the test meal, intra-individual and inter-individual coefficients of variation (COVs), and the ability of the GEBT breath percent dose excreted \*1000 values to predict scintigraphic half-life and to categorize GE as delayed, normal, or accelerated. In healthy group, the 10th and 90th percentiles of half-life for scintigraphic GE with this meal were 52 and 86 minutes; intra-individual COVs for scintigraphy and the GEBT were, respectively, 31% and 27% at 45 minutes, 17% and 21% at 90 minutes, 13% and 16% at 120 minutes, 10% and 13% at 150 minutes, and 8% and 12% at 180 minutes. The inter-individual COVs at each time for the [<sup>13</sup>C] GEBT and scintigraphy were typically approximately 1%-4% lower than intra-individual COVs. Individual breath samples at 45, 150, and 180 minutes predicted GE category; at 80% specificity, 45- and 180-minute samples combined were 93% sensitive to identify accelerated GE, and 150- and 180-minute combined were 89% sensitive for delayed GE.

### **U.S. Food and Drug Administration (FDA)**

<sup>13</sup>C-Spirulina Platensis Gastric Emptying Breath Test (Gastric Emptying Breath Test, [GEBT]) (Advanced Breath Diagnostics LLC, Brentwood TN) received premarket approval (PMA) April 2015. The Gastric Emptying Breath Test (GEBT), to be used with the GEBT test meal, is intended for use in the measurement of the rate of gastric emptying of solids and as an aid in the diagnosis of delayed gastric emptying (gastroparesis) in adult humans who are symptomatic for gastroparesis.

Contraindications include:

- Individuals with known hypersensitivity to Spirulina, egg, milk or wheat allergens should avoid the GEBT.
- Because the GEBT is an indirect multi-compartmental method of measuring gastric emptying, GEBT results may be inaccurate in individuals compromised with significant small bowel, pancreatic, liver and/or lung disease. Consequently GEBT should not be administered to patients with pulmonary dysfunction (e.g. COPD) and/or small bowel malabsorption.

Approval was based on the observation in a study of 115 patients who underwent simultaneous scintigraphy and spirulina <sup>13</sup>C breath test. At 80 percent specificity, the <sup>13</sup>C-spirulina breath test samples at 150 and 180 minutes had a combined sensitivity of 89 percent for delayed gastric emptying.

### **Professional Societies/Organizations**

**American College of Gastroenterology (ACG):** ACG published clinical guidelines for management of gastroparesis. The recommendations include, "Alternative approaches for assessment of gastric emptying include wireless capsule motility testing and <sup>13</sup>C breath testing using octanoate or spirulina incorporated into a solid meal; they require further validation before they can be considered as alternates to scintigraphy for the diagnosis of gastroparesis. (Conditional recommendation, moderate level of evidence)"

## **Neurology**

### **Quantitative Sensory Testing (QST) (CPT Codes 0106T, 0107T, 0108T, 0109T, 0110T; HCPCS Code G0255)**

QST is a psychophysical test used to assess and quantify small and large-fiber sensory nerve function by the use of touch, thermal (i.e., hot and cold), pain, and/or vibratory sensations. QST, a noninvasive study, is proposed to be able to detect early, subtle changes in small and large sensory nerve fibers. It has been proposed as a complementary diagnostic and monitoring tool to be used with traditional testing (e.g., Semmes-Weinstein monofilaments, Rydel Seiffert graduated tuning fork) for the detection of sensory nerve abnormalities for conditions such as diabetic neuropathy, carpal tunnel syndrome, multiple sclerosis and vitamin B deficiencies. QST has also been proposed for multiple other indications including: identifying HIV-associated peripheral neuropathy, use before and after lumbar discectomy to analyze sensory nerve dysfunction in the lower-extremities, following greater saphenous vein stripping to evaluate postoperative sensory changes, and prior to and following spinal cord stimulation for patients with chronic neuropathic pain due to either failed back surgery syndrome or complex regional pain syndrome, evaluation of sexual dysfunction, peripheral nerve dysfunction, painful bladder syndrome, and radiculopathy.

Several limitations of QST have been documented including a potential for bias if the patient is cognitively impaired or desires an abnormal result. QST has no localizing value because it is reflective of the integrity of the entire sensory neuraxis from receptors to brain. Abnormal QST values may occur because of peripheral nerve or central nervous system dysfunction. The test may lack objectivity due to patient status (e.g., distraction, boredom, inattention, fatigue, drowsiness), which may be enhanced by the time it takes to complete the test (e.g., one to two hours). The inclusion of the patient's reaction time to a stimulus may distort the actual sensory threshold. Electrode size, site of stimulation, method and rate of change of the stimulation, method of obtaining patient's response, and variations in testing devices make reproducibility of the test results difficult. There is also a lack of standardization for testing procedures and reporting outcomes, therefore test execution may differ with different examiners. Due to these variables, it is proposed that quantitative sensory testing (QST) lacks the objectivity of conventional nerve conduction studies (Pavlovic, et al., 2010; Backonja, et al., 2009; Siemionow, et al., 2006; Chong, et al., 2004; Shy, et al., 2003).

The various testing methods and devices used for QST to determine sensory abnormalities include:

- Electrical current testing such as current perception threshold testing or sensory nerve conduction testing (sNCT) which assesses sensory function. Examples of these devices include the Medi-DX 7000 (Neuro-Diagnostic Associates, Laguna Beach, CA) and the Neurometer® CPT or s-NCT (Neurotron, Inc., Baltimore, MD).
- Pressure-specified sensory testing evaluates nerve function by detection of light, status, and moving touch. Devices include the NK Pressure-Specified Sensory Device™ (PSSD) (NK Biotechnical Engineering Co., Minneapolis, MN).
- Thermal testing is used to assess a distinction between predominantly C fiber and A-delta fiber activity by the application of cold and heat. Examples of thermal devices by Medoc Advanced Medical Systems LTD (Minneapolis, MN) include the Contact Heat-Evoked Potential Stimulator (CHEPS), GSA Genito, TSA-2001 Sensory Analyzer, and the TSA-2001 Sensory Analyzer.
- Vibration perception threshold testing, or vibratory testing, assesses large myelinated nerve fiber dysfunction and measures sensory thresholds. The VSA-3000 Vibratory Sensory Analyzer (Medoc Advanced Medical Systems, Eilat, Israel) and the Bio-thesiometer (Bio-Medical Instruments, Newbury, OH) are examples of these devices.

- Voltage-actuated sensory nerve conduction threshold (V-sNCT) testing is used to evaluate the sensitivity, specificity and predictive value of A-delta fibers to assess localized pain sources. These devices include the Neural-Scan (Neuro-Diagnostic Associates [NDA], Inc., Laguna Beach, CA).
- Pain-fiber nerve conduction testing (pf NCV), also referred to as pain fiber nerve testing, has been proposed as a method of evaluating the severity, location and distribution of pain associated with conditions such as radiculopathy and/or neuropathy. According to the American Association of Sensory Electrodiagnostic Medicine (AASEM, 2015), this type of nerve testing is noninvasive, employs the use of a device, such as the Axon II, Neural Scan, and is conducted using a voltage actuated stimulus (sensory nerve conduction) and a potentiometer to measure the amplitude of the action potential.

**U.S. Food and Drug Administration (FDA):** QST systems and devices are approved by the FDA 510(k) process and are classified either as a Class II device or an unclassified device.

### Literature Review

Hayes published a technology directory report regarding quantitative sensory testing for the diagnosis of lower extremity peripheral neuropathy (Hayes 2014; 2017). The review included 29 prospective or retrospective cohort, cross-sectional, matched-group, or case-control studies that evaluated QST for detection of neuropathy or foot ulcer and/or amputation susceptibility. There were no studies identified that relied on QST to guide patient management. Findings of the report noted that all of the available studies of QST are of poor to very poor quality and the amount and consistency of evidence concerning QST for the diagnosis of neuropathy varies widely, depending on the type of QST and the indication for testing. Some evidence suggests that vibration QST has moderate to high accuracy for the diagnosis of neuropathy and that monofilament QST and vibration QST have moderate to high accuracy for the diagnosis of loss of protective sensation as reflected in susceptibility to foot ulcer and/or amputation as a consequence of neuropathy. It was noted that there is insufficient evidence to evaluate monofilament QST for the diagnosis of neuropathy or to evaluate thermal QST, ball bearing QST, 2-point discrimination QST, or tactile circumferential QST for the diagnosis of neuropathy or susceptibility to foot ulcer and/or amputation. The report concluded that the best available studies do not provide consistent evidence that quantitative sensory testing (QST) has high accuracy for the diagnosis of neuropathy or loss of protective sensation.

The clinical significance of QST has not been demonstrated in clinical trials (Atherton, et al., 2007; Soomekh, et al., 2006; Chong, et al., 2004; Shy, et al., 2003). Additionally, evidence in the published peer-reviewed scientific literature does not support the clinical utility of QST. Randomized controlled clinical trial data are scarce; studies are primarily in the form of nonrandomized comparative studies and case series with heterogeneous small patient populations, using a variety of different devices. QST has not been recommended as a stand alone test. Limitations of the studies include: weak study methodology; inability to verify data; lack of a control group; numbers of patients lost to follow-up; numbers of patients who did not complete all of the testing; lack of comparisons to conventional neurological tools; variations in testing parameters, equipment and protocol; and lack of randomization (Eisenberg, et al., 2006; England, et al., 2005/2008; Centers for Medicare and Medicaid Services, 2003).

### Professional Societies/Organizations

**American Academy of Orthopedic Surgeons (AAOS):** In their guidelines on the diagnosis of carpal tunnel syndrome, AAOS (2007) noted that the physician should not routinely evaluate patients with suspected carpal tunnel syndrome with new technology such as pressure specified sensorimotor devices.

**American Academy of Neurology (AAN):** In a report on QST based on a review of 350 articles, the AAN (Shy, et al., 2003; reaffirmed 2008 and 2013) noted QST is a potentially useful tool for measuring sensory impairment for clinical and research studies. However, QST results should not be the sole criteria used to diagnose pathology". The AAN indicated that malingering and other nonorganic factors can affect the outcomes of the test results. They also noted that well-designed studies to compare the various types of QST devices and methodologies are indicated and should include patients with abnormalities detected solely by QST.

In a report on distal symmetric polyneuropathy (England, et al., 2005; reaffirmed 2008), the American Academy of Neurology, the American Association of Electrodiagnostic Medicine, and the American Academy of Physical Medicine and Rehabilitation stated that QST was not recommended as a diagnostic tool because the sensitivities

and specificities varied widely among the studies, and the tests have inherent variability. QST is difficult to standardize, and reproducibility of results ranged from poor to excellent.

**American Association of Electrodiagnostic Medicine (AAEM):** The AAEM (Chong, et al., 2004) conducted a review of the literature on QST to assess the “methodology, reliability, reproducibility, limitations, and potential clinical applications” of these studies. The authors noted the following conclusions:

- QST is a reliable psychophysical test of large- and small-fiber sensory modalities.
- QST tests the integrity of the entire sensory axis from receptors to brain. Abnormalities do not localize dysfunction to the central or peripheral nervous system, or any particular location along the peripheral nervous system.
- QST is highly dependent on the full cooperation of the patient and may be falsely abnormal if the patient is biased toward an abnormal result or is cognitively impaired. No algorithm can reliably distinguish between psychogenic and organic abnormality.
- QST has been shown to be reasonably reproducible over a period of days or weeks in normal subjects. Since longitudinal QST studies of patients in drug trials are usually done over a period of several months to a few years, reproducibility studies on the placebo-controlled group should be included.
- The reproducibility of thermal thresholds may not be as good as that of vibration threshold.
- For individual patients, more studies are needed to determine the maximum allowable difference between two QSTs that can be attributed to experimental error.
- Different commercially available QST instruments have different specifications (thermode size, stimulus characteristics), testing protocols, algorithms, and normal values. Only QST instruments and their corresponding methodologies that have been shown to be reproducible should be used for research and patient care.
- The results of QST can only be interpreted properly if machine calibration and testing protocol are strictly followed.
- The literature does not allow a conclusion to be made regarding whether any QST instrument is better than another.

#### **Use Outside of the US**

**European Federation Of Neurological Societies (EFNS):** In their 2009 guidelines (Cruccu, 2009) on the assessment of neuropathic pain, EFNS stated that studies using qualitative sensory testing (QST) lack blinding, involve a broad spectrum of patients and controls, and only four of 50 new studies were prospective. The variability of methods, results, and patient populations (e.g., diabetic neuropathy, spinal cord injury, radiculopathy) prevent any conclusions from being drawn. The Society stated that qualitative sensory testing (QST) may be used to document the sensory profile, but the test “cannot be considered sufficient to separate differential diagnoses”. “Quantitative sensory testing (QST) is helpful to quantify the effects of treatments on allodynia and hyperalgesia and may reveal a differential efficacy of treatments on different pain components”. They “do not recommend the systematic measure of thermal stimuli except for pathophysiological research or treatment trials. A simple and sensitive tool to quantify pain induced by thermal stimuli in clinical practice is still lacking”.

**International Association for the Study of Pain (IASP®):** In guidelines on neuropathic pain assessment (Haanpää, 2011), the Special Interest Group on Neuropathic Pain of the IASP (NeuPSIG) explains that QST is biased towards thermal, including nociceptive, testing, which means that it excludes assessment of large fiber function. According to NeuPSIG, more studies with complete somatosensory profiles are needed. Results of available studies have been inconsistent and conflicting. Since QST abnormalities are found in non-neuropathic pains, these tests cannot be taken as a conclusive demonstration of neuropathic pain. Further, NeuPSIG notes QST can be used in clinic along with bedside testing, but it cannot allow for estimation of the level of the lesion within the neuraxis. The relevance of QST to predict therapeutic outcome has yet to be established in prospective studies.

### **Physiologic Recording of Tremor Using Accelerometer/Gyroscope (CPT Code 95999)**

Accelerometers and gyroscopes are devices that may be used to objectively record and monitor motion and electrical activity of muscles to measure tremor in individuals with movement disorders. Recent studies have examined the clinical utility of these devices as an adjunct in diagnosis and measurement of functional ability and recovery in individuals with dyskenetic disorders.

### **U.S. Food and Drug Administration (FDA)**

The FDA approved the Kinesia™ device (Cleveland Medical Service, Cleveland, OH) in April 2007 for the monitoring and recording of motion and electrical activity of muscle to quantify kinematics of movement disorders such as tremor for research and diagnostic purposes. The Tremorometer® (FlexAble Systems, Inc., Fountain Hills, AZ) received substantial equivalency FDA 510 (k) approval in January 2001. It is a system designed to improve the measurement and quantification of tremor in human patients regardless of the etiology.

### **Literature Review**

Controlled clinical trial data are lacking to inform the utility of these devices, including the translation of measurements into meaningful outcomes. Cheung et al. (2011) performed a systematic literature review; reviewing 54 studies that used accelerometers to classify human movement and to appraise their potential to determine the level of activity of older persons in hospital settings. Outcome measures criteria were comparisons of derived classifications of postural movements and mobility against those made by using observations. A number of limitations to the study were noted including the number and type of accelerometers used for measurement, varied age of study participants (varied from teenager to >60 yrs). Most studies were limited by small sample size; 54% had 10 subjects or less. Methods for validating data were also varied. Of the accelerometer studies included in this review, only 17 were conducted on patients and the remaining were conducted on healthy subjects (n=37 studies). The authors note that the literature review indicates that only a limited number of studies have applied accelerometry to measure activities in patients, of which six studies were of older patients. These studies were limited by smaller sample sizes and use of multiple accelerometer devices attached to different body positions. The activity classification algorithms validated in small sample size studies with <6 patients are insufficient for clinical use. A suitable algorithm for application in geriatric rehabilitation settings needs to be generic and accurate in older patients with different levels of mobility impairment.

Gebruers et al. (2010) reported results of a systematic review assessing the clinical applicability of different accelerometry based measurement techniques in persons with stroke. Twenty-five articles were selected for inclusion; there were 4 randomized controlled trials (RCT). The authors noted that although the available evidence may suggest that accelerometers yield valid and reliable data about individuals with stroke, data are young, limiting the ability to draw consistent conclusions. Further research is necessary to investigate predictive value and responsiveness.

### **Adrenal and Fetal Mesencephalic Transplantation for Parkinson Disease (HCPCS Code S2103)**

There are scarce data in the published, peer-reviewed scientific literature regarding the current clinical use of adrenal-to-brain transplantation in humans for any indication. In a systematic review of the literature, the Agency for Healthcare Research and Quality ([AHRQ], 2003) noted that there is a lack of efficacy and substantial morbidity associated with the procedure for the treatment of Parkinson disease (PD). The AHRQ also concluded that adrenal medullary transplants are no longer performed to treat PD.

There is ongoing research in animal and human models relative to the use of fetal mesencephalic transplantation as a replacement source of dopamine-producing cells. In this procedure, fetal brain cells (i.e., neurons) that produce dopamine are implanted in the putamen or head of the caudate area of the brain, which is the area controlling movement. In theory, the transplanted neurons can replace the loss of normal dopamine-producing cells. These fetal cells may be human or xenogeneic (i.e., derived from a different species).

Clinical improvement was demonstrated in small numbers of individuals with PD undergoing transplantation of fetal tissue in several nonrandomized studies; however, results have not been replicated in double-blind sham-surgery controlled clinical trials (Olanow, 2003; Freed, 2001). Transplantation of fetal substantia nigra into the stratum has failed to show significant efficacy and has been associated with the side effect of transplant-induced off-medication dyskinesias. More recently, implanted dopamine neurons have been found to contain Lewy bodies, suggesting that they are dysfunctional and may have been affected by the PD pathological process (Olanow, 2009).

The data is scarce regarding the safety and effectiveness of xenogeneic fetal cells for any indication in humans. Schumacher et al. (2000) reported results of a case series study of 12 individuals with Parkinson disease who underwent unilateral implantation of embryonic porcine ventral mesencephalic tissue (Schumacher, 2000). In the medication-off state, total Unified Parkinson's Disease Rating Scale scores improved by 19% ( $p=.01$ ). At the time of study publication there were no reported permanent complications. Limitations of the study include small size, uncontrolled study design, and short-term follow-up.

### **U.S. Food and Drug Administration (FDA)**

The FDA Center for Biologics and Research regulates the transplantation of fetal/embryonic cells. Companies supplying cell and tissue-based products must register and list their products with the FDA.

### **Professional Societies/Organizations**

**American Academy of Neurology (AAN):** The AAN in an evaluation of surgery for Parkinson's disease (Hallett, et al., 1999) recommended that adrenal-to-brain transplantation not be performed because of unacceptable risk to the patient. They further noted that the procedure was no longer being studied. Regarding fetal mesencephalic transplantation the AAN notes that, while the procedure is promising, it remains experimental due to lack of controlled clinical trials. The authors determined that there were small, nonrandomized case studies which noted functional improvement in some patients; however, unacceptably high levels of morbidity and mortality were associated with the procedure. Review of pathologic reports found that few transplanted cells survived long term, suggesting that benefit of the procedure would be of short duration.

The authors also reviewed the documented studies of fetal mesencephalic transplantation. Studies were small and nonrandomized. There was variation between the studies in the techniques utilized, the site of transplantation, the number of mesencephalons used, and the immune-suppressive regimen provided. In all of the studies some of the patients demonstrated improvement in motor function. The summary notes that while the

procedure is promising because it appears effective and has low morbidity and mortality, it is considered experimental because of the absence of controlled studies.

### **Whole Body and Select Head Hypothermia in the Neonate (CPT Code 99184)**

Hypoxic ischemic encephalopathy is characterized by the need for resuscitation at birth, neurologic depression, seizures, and electroencephalographic abnormalities. No specific clinical intervention has been shown to alter outcome. Total body and selective head hypothermia (e.g., a reduction in brain temperature of two-five degrees) in the neonatal population have been proposed as a therapeutic intervention to reduce death as well as neurodevelopmental disabilities.

According to Gluckman et al. (2005) the neuroprotective effects of experimental cooling are dependent on both a sufficient duration of cooling and on the timing of initiation of cooling. Extended cooling for 24–72 hours, started as late as six hours after injury, has been associated with persistent protection.

### **Literature Review**

Jacobs et al. (2013) reported on a Cochrane review regarding cooling for newborns with hypoxic ischemic encephalopathy to determine the effect of therapeutic hypothermia in encephalopathic asphyxiated newborn infants on mortality, long-term neurodevelopmental disability and clinically important side effects. The review included 11 randomized, controlled studies (=1505) with term and late preterm infants with moderate/severe encephalopathy and evidence of intrapartum asphyxia that compared the use of therapeutic hypothermia with standard care. The authors concluded that there is evidence from the trials included in the systematic review that therapeutic hypothermia is beneficial in term and late preterm newborns with hypoxic ischemic encephalopathy. They noted that cooling reduces mortality without increasing major disability in survivors. The benefits of cooling on survival and neurodevelopment outweigh the short-term adverse effects. The authors note that hypothermia should be instituted in term and late preterm infants with moderate-to-severe hypoxic ischemic encephalopathy if identified before six hours of age.

Shankaran et al (2005) reported results of a randomized controlled clinical trial of hypothermia in infants with a gestational age of at least 36 weeks who were admitted to the hospital at, or before six hours of age with either severe acidosis or peri-natal complications and resuscitation at birth. The infants had moderate or severe encephalopathy. Study participants were randomly assigned to standard care (control, n=106) or whole body cooling (i.e., esophageal temperature of 33.5 degrees Celsius for 72 hours, followed by slow re-warming, hypothermia group, n=102). Neurodevelopmental outcome was assessed at 18 to 22 months of age. The primary outcome was death or severe disability. Death or moderate or severe disability occurred in 44 % in the hypothermia group and 62 % of infants in the control group ( $p = 0.01$ ). Twenty-four and 38 infants died in the hypothermia and control groups, respectively, ( $p = 0.08$ ). The rate of cerebral palsy was 19% and 30% in the hypothermia and control groups, respectively ( $p = 0.20$ ). Data suggest that whole-body hypothermia reduces the risk of death or disability in this patient population.

In a follow-up to this study Shankaran et al. (2012) reported long-term outcomes of evaluable study participants. Of the 208 trial participants, primary outcome data were available for 190. Of the 97 children in the hypothermia group and the 93 children in the control group, death or an intelligence quotient (IQ) score below 70 occurred in 46 and 58, respectively ( $p=0.06$ ). In these same groups, death occurred in 27 and 41, respectively, in the hypothermia and control groups ( $p=0.04$ ). Death or severe disability occurred in 38 and 53, respectively, in the hypothermia and control groups ( $p=0.03$ ). The rate of the combined end point of death or an IQ score of less than 70 at six to seven years of age was lower among children undergoing whole-body hypothermia than among those undergoing usual care. Outcomes were not statistically significant. Data suggest that hypothermia results in lower death rates; the rates of severe disability among survivors did not increase in the group undergoing hypothermia.

Azzopardi et al. (2009) performed a randomized controlled study of infants who were less than six hours of age and had a gestational age of at least 36 weeks and peri-natal encephalopathy. The study compared outcomes for infants receiving intensive care plus whole body hypothermia 33.5 degrees Celsius for 72 hours (n=163) with intensive care alone (n=162). The primary outcome was death or severe disability at 18 months of age. In the group undergoing hypothermia 42 infants died; 32 infants survived but had severe neurodevelopmental disability. In the intensive care treatment arm 44 infants died and 42 had severe disability ( $p = 0.17$ ). Infants in the cooled group had an increased survival without neurological abnormality ( $p = 0.003$ ). Among survivors, cooling resulted in reduced risks of cerebral palsy ( $p = 0.03$ ) and improved scores on the Mental Developmental and Psychomotor Developmental Indexes of the Bayley Scales of Infant Development II ( $p = 0.03$  for each) and the Gross Motor Function Classification System ( $p = 0.01$ ). Data suggest that moderate hypothermia for 72 hours did not significantly reduce the combined rate of death or severe disability but resulted in improved neurological outcomes in survivors who received hypothermia.

In a multi-center randomized controlled trial Zhou et al (2010) examined the safety and the effectiveness of selective head cooling (SHC) with mild systemic hypothermia (i.e., nasopharyngeal temperature of 34 $\pm$ 0.2 C and rectal temperature of 34.5-35.0 Celsius for 72 hours) in infants with hypoxic ischemic encephalopathy (HIE). Infants were randomly assigned to the SHC or the control group. SHC was initiated within six hours after birth for infants in the hypothermia group. Rectal temperature was maintained at 36.0 to 37.5 degrees Celsius in the control group. Neurodevelopmental outcome was assessed at 18 months of age. The primary outcome was a combined end point of death and severe disability. The combined outcome of death and severe disability, mortality rate, and severe disability rates were significant ( $p = 0.01$ ;  $p = 0.16$ ; and  $p = 0.01$ ) for the SHC and control groups, respectively. Data suggest that SHC with mild systemic hypothermia may significantly decrease the combined outcome of severe disability and death, as well as severe disability.

### **Professional Societies/Organizations**

**American Heart Association (AHA):** In a special report, the AHA published Neonatal Resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Kattwinkel, et al., 2010). Regarding therapeutic induced hypothermia the AHA recommendation notes that infants born at  $\geq 36$  weeks gestation with evolving moderate to severe hypoxic ischemic encephalopathy should be offered therapeutic hypothermia. The treatment should be implemented according to the studied protocols, which currently include commencement within six hours following birth, continuation for 72 hours, and slow rewarming over at least four hours. Further, therapeutic hypothermia should be administered under clearly

defined protocols similar to those used in published clinical trials and in facilities with the capabilities for multidisciplinary care and longitudinal follow-up.

#### **Percutaneous or Open Implantation of Electrode Array (CPT codes 64999)**

Percutaneous or open implantation of a neurostimulator electrode array is a technique being investigated for treatment of chronic pain where stimulation is delivered by a pulse generator and an electrode that is placed subcutaneously at the site of maximum pain rather than at the site of the nerve. This technique also referred to as subcutaneous target stimulation (STS) or peripheral nerve field stimulation (PNFS) involves a temporary trial period in which an electrode is placed subcutaneously by open or percutaneous approach, is secured in place with suture, and is then attached to a generator for approximately two to 14 days. A trial is considered successful if there is at least 50% pain reduction. Following a successful temporary trial the device is implanted

**U.S. Food and Drug Administration (FDA):** FDA approval for specific PNFS devices was not found on the FDA site. However, PNFS can be carried out using leads and electrodes that are primarily designed for spinal cord stimulation and may be considered an off-label use of these devices.

#### **Literature Review**

Randomized controlled clinical trial data, and meta-analyses are lacking in the published, peer-reviewed scientific literature and there is insufficient evidence to determine safety and effectiveness of this therapy. Published peer-reviewed clinical trial data is primarily limited to case series and retrospective reviews.

#### **Use outside of the US**

The National Institute for Health and Care Excellence (UK, [NICE], 2013) published guidance regarding peripheral field nerve stimulation for chronic low back pain. NICE recommendations note that evidence on efficacy is very limited, in both quality and quantity. Likewise, evidence on safety is also limited and there is a risk of complications from any implanted device. Therefore this procedure should only be used with special arrangements for clinical governance, consent and audit or research.

### **External Heart Rate and 3-Axis Accelerometer Monitoring to Diagnose Nocturnal Epilepsy (CPT Codes 0381T, 0382T, 0383T, 0384T, 0385T, 0386T)**

Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures (Abou-Khalil, 2012). Standard evaluation and diagnosis of seizures and epilepsy includes an in-depth clinical history; an electroencephalogram and other brain imaging may be used to supplement the history, help classify the type of seizure and determine underlying pathology. A number of epileptic seizure syndromes exist including several which are characterized by the occurrence of seizures at night, while the individual is sleeping and unattended. Nocturnal seizures often occur in children. Use of external heart rate and 3-axis accelerometer monitoring has been proposed as a method to detect/diagnose nocturnal epilepsy. Three-axial accelerometer measures the movement (acceleration) in three orthogonal directions fixed to a sensor by way of soft bands generally affixed to the wrists and/or ankles.

### **Literature Review**

Published, peer-reviewed data are limited regarding the effectiveness of accelerometer monitoring to diagnose epilepsy, including nocturnal epilepsy (Beniczky, 2013; Van de Vel, 2013). Studies are limited by uncontrolled design, small participant numbers and short-term follow-up.

Beniczky et al. (2013) reported outcomes of a prospective study designed to assess the clinical reliability of a wrist-worn, wireless accelerometer sensor for detecting generalized tonic-clonic seizures in 73 consecutive patients. The wireless wrist accelerometer correctly detected 35 seizures (89.7%). The mean sensitivity per patient (with seizure) was 91%. Twenty-eight seizures occurred during sleep and eleven seizures occurred when the patient was awake. The device had a similar accuracy for detecting nocturnal and daytime seizures. One hundred forty-nine seizures other than generalized tonic-clonic seizures were recorded (simple partial, 37; complex partial/psychomotor, 31; focal tonic, 6; hypermotor, 6; absence, 1; myoclonus, 60; psychogenic nonepileptic seizure, 8). Study limitations include uncontrolled design, small study numbers and short-term follow-up.

### **Laparoscopic Radiofrequency Ablation (RFA) of Uterine Fibroids (CPT codes 58674)**

Laparoscopic RFA has been proposed for the treatment of uterine fibroids of all sizes. In this minimally invasive procedure a laparoscopic ultrasound probe is used to determine the location and size of fibroids. An electrode array delivers alternating radiofrequency energy to drive a current through the tissue to be ablated, causing controlled, local heating, resulting in targeted tissue destruction.

**U.S. Food and Drug Administration (FDA):** The Acessa System (Halt Medical, Inc., Brentwood, CA) was given 510(k) approval in November 2012. According to the approval summary this system is indicated for use in percutaneous, laparoscopic coagulation and ablation of soft tissue, including treatment of symptomatic uterine fibroids under laparoscopic ultrasound guidance. The FDA specifically notes the Acessa System must be used under laparoscopic ultrasound guidance. Laparoscopic ultrasound equipment is not included with the Acessa System.

### **Literature Review**

Peer-reviewed published clinical trial data are limited to a single small randomized controlled trial of 51 women with 26 subjects in the RFA treatment arm (Brucker, 2014; Hahn, et al., 2015; Kramer, et al., 2016) and several nonrandomized, uncontrolled prospective studies, also with small participant numbers. Chudnoff et al. (2013), Guido et al. (2013) and Berman et al. (2014) reported 12-, 24- and 36-month follow-up of the same nonrandomized prospective interventional trial involving 135 women with symptomatic uterine fibroids. These studies are limited by uncontrolled, nonrandomized study design, small size and lack of comparison to other treatment methods. Several randomized controlled studies are ongoing.

Brucker et al. (2014) reported outcomes of a randomized, prospective single-center international clinical trial involving 51 women comparing radiofrequency volumetric thermal ablation (RFVTA) (n=26) and laparoscopic myomectomy (LM) (n=25) for symptomatic uterine fibroids. Primary outcomes were the mean hospital discharge times and perioperative outcomes. The predominant symptom reported by the patients in both groups was heavy menstrual bleeding followed by urinary frequency, pelvic discomfort and pain, backache, localized pain, dysmenorrhea, urinary retention, increased abdominal girth, dyspareunia, uterine pain, and sleep disturbance. There were no significant differences based on Fisher exact test between the two groups with regard to any of these symptoms, although the authors note this could be because of the relatively small number of patients in each group. Surgeons were blinded to the treatment until all fibroids were mapped by laparoscopic ultrasound. The mean hospitalization times were 10.0± 5.5 hours for the RFVTA group and 29.9 ± 14.2 hours for the LM group (p=.16). Intraoperative blood loss was 16 mL for the RFVTA procedures and 51 mL for the LM procedures. The percentage of fibroids imaged by laparoscopic ultrasound that were treated/excised was 98.6% for RFVTA and 80.3% for LM. Two complications were reported: vertigo (n=1; RFVTA) and port site hematoma (n=1; LM).

The mean time between arrival in post-anesthesia recovery and discharge from the hospital was 8.2 hours for the RFVTA group and 28.0 hours for the LM group ( $p < 0.001$ ). Mean hospitalization time was 10.0 hours and 29.9 hours for the RFVTA and LM groups, respectively,  $p < 0.001$ . The authors note that short-term follow-up is a limitation to the study and plan five-year follow-up for pregnancy outcomes, symptom improvement, and overall treatment satisfaction as evaluated on the basis of participants' responses to validated questionnaires. The study is limited by small study participant numbers.

Hahn et al. (2015) published one year results of the above study (Brucker, et al., 2014) with objective to analyze, compare and describe the study's three, six and twelve month outcomes in terms of pain medication use, recovery from surgery, and subjects' subjective responses to validated questionnaires. The results included: post-surgery, ablation and myomectomy subjects took pain medications for 4 days (range: 1–46) and 7 days (range: 1–83 days) respectively ( $p = 0.60$ ); ablation and myomectomy patients missed 10.0 workdays (range: 2–86 days) and 17.0 workdays (range: 7–30 days) ( $p = 0.28$ ); resumed normal activities in 20.5 days (range: 5–103 days) versus 28.0 days (range: 10–42 days) ( $p = 0.86$ ) respectively. The mean symptom severity scores decreased (improved) by  $-7.8$  for the ablation subjects and by  $-17.9$  for the myomectomy subjects ( $p = 0.16$ ). Health-related quality of life improved (increased) by 7.5 and 13.1, respectively, for the two groups ( $p = 0.46$ ). Two myomectomy subjects had pregnancies that ended in a Cesarean delivery and a vaginal delivery of healthy infants. Two pregnancies in the RFVTA group ended in full-term vaginal deliveries of healthy infants. The authors concluded that early postoperative recovery and twelve-month results indicate similar efficacy, quality of life, and safety for both treatment groups. The subjects will be continued to be followed for five years.

Kramer et al. (2016) reported on 24 month data from the above study (Brucker, et al., 2014). The outcomes included this analysis were patients' responses to validated questionnaires and long-term safety. The study included 51 patients with 21 and 22 patients in the RFVTA and laparoscopic myomectomy groups, respectively that completed 24 months of follow-up. There was improvement reported in the severity of symptoms from baseline by participants in both the RFVTA ( $P < 0.001$ ) and laparoscopic myomectomy groups ( $P = 0.001$ ). The study observed a significant improvement in health-related quality of life in the laparoscopic myomectomy group ( $P = 0.040$ ); and a non-significant improvement was noted in the RFVTA group ( $P = 0.083$ ). A trocar-site hematoma occurred in one patient in the laparoscopic myomectomy group. There were further surgical interventions recorded in three patients in the RFVTA group but it was noted that these were unrelated to fibroid symptoms.

Hayes evaluated the safety and efficacy the Acessa System for treatment of uterine fibroids (Hayes, 2014; 2017). They noted that the all of the included studies found significant benefits of treatment of uterine fibroids with the Acessa System, and longer-term studies demonstrated the durability of the treatment effect. Treatment reduced pain, heavy bleeding, and other symptoms, and improved quality of life. They found that the overall quality of the evidence is low. Five of the six studies lacked a control group, and the single, randomized, clinical trial only reported on perioperative outcomes with no long-term follow-up. Many of the study endpoints were subjective. Additional studies evaluating larger populations and that include control groups and head-to-head comparisons with other treatments for uterine fibroids are warranted to determine the optimal clinical role of this technology.

Chudnoff et al. (2013) reported one year results of a prospective, multicenter, interventional clinical trial (i.e., HALT trial) with primary outcome measures of change from baseline to 12 months and ongoing qualitative follow-up of women for three years in a cohort of 135 premenopausal symptomatic women with uterine myomas, uteri 14 weeks of gestation-sized or less with no single myoma exceeding 7 cm, and objectively confirmed heavy menstrual bleeding. Primary intervention was outpatient laparoscopic ultrasound-guided radiofrequency volumetric thermal ablation using the Acessa system (Halt Medical, Brentwood, CA). Bleeding outcomes and validated quality-of-life and patient satisfaction scales and objective measurements of uterine and myoma volume were conducted at 3, 6, and 12 months. Mean alkaline hematin and associated menstrual blood loss decreased from baseline levels by 31.8%, 40.7%, and 38.3%, respectively, at three-, six-, and 12-month intervals ( $p < .001$  for all). Symptom severity and health-related quality of life improved ( $p < .001$ ). There was one serious adverse event (0.7%) requiring readmission 5 weeks post-procedure and one surgical reintervention for persistent bleeding. Ninety-four percent of the women reported satisfaction with the treatment ( $p < .001$ ). The study was limited by uncontrolled design, short-term follow-up and a lack of comparison to other treatment methods.

In a follow-up to the study by Chudnoff et al. (2013), Guido et al. (2013) reported two-year outcomes of 124 subjects who participated in the HALT trial, of whom 112 were evaluable. Outcome measures included: subject responses to validated questionnaires, treatment-emergent adverse events, and surgical re-intervention for fibroids at 24 months post-procedure. Significant changes from baseline were noted in symptom severity ( $p < .001$ ) and health-related quality of life scores ( $p < .001$ ). There was a significant improvement in the mean health state score between baseline and 3 months after treatment ( $p < .001$ ). Measurements at subsequent intervals showed no continued improvement. Six patients underwent surgical reintervention for fibroid-related bleeding between 12 and 24 months. The authors also reported on one patient who had an episode of bleeding post Cesarean section requiring receipt of six units of blood, which the study authors noted as possibly related to the RFA procedure. Limitations to the study include uncontrolled design, lack of comparator, short-term follow-up and small total patient numbers.

In a thirty-six month follow-up study, Berman et al. (2014) reported subject responses to validated questionnaires and surgical repeat intervention to treat myomas outcomes for a cohort of 104 evaluable patients (104/135) who participated in the HALT trial. Change in mean symptom severity ( $p < .001$ ) and Health-Related Quality of Life questionnaire scores ( $p < .001$ ) were improved from the baseline. Patient-reported Uterine Fibroid Symptom and Health-Related Quality of Life questionnaire subscores demonstrated statistically significant improvement from baseline to 36 months ( $p < .001$ ) in all categories (i.e., Concern, Activities, Energy/Mood, Control, Self-consciousness, and Sexual Function). The cumulative repeat intervention rate was of 11% at 36 months. Although results are promising, study limitations include uncontrolled, nonrandomized design, lack of comparison to other treatment methods, and small study participant numbers.

Robles et al. (2013) assessed outcomes of a prospective study assessing the laparoscopic radiofrequency volumetric thermal ablation (RFVTA) system among 114 screened women with symptomatic myomas. Thirty-five women completed the 12-month follow-up period. Uterine fibroid symptom and health-related quality-of-life (UFS-QOL) questionnaires were completed at zero, three-, six-, and 12-months. There was a significant reduction in average symptom severity score over the study period ( $p < 0.001$ ), and reductions in symptom severity scores from baseline to each of the follow-up visits, and from the 3-month visit to the 12-month follow-up visit were significant ( $p < 0.001$ ). There was a significant increase in average health-related quality of life (HRQL) scores from baseline to 12 months ( $p < 0.001$ ) and in the HRQL scores from baseline to each of the follow-up visits ( $p < 0.001$ ). After discharge, none of the participants was admitted to hospital for procedure-related complications. Within the study period, none of the participants required hysterectomy or any myoma treatment after RFVTA. No transfusions were required. Nine adverse events among eight women were reported as definitely not device- or procedure-related. Study limitations which limit the ability to routine clinical practice include lack of randomization and control, small study population, short-term follow-up of 12 months and lack of comparison to other treatment methods.

Thirty-one women with symptomatic uterine fibroids underwent outpatient laparoscopic, ultrasound-guided, radiofrequency volumetric thermal ablation using the Halt 2000 System. Postoperative follow-up occurred at three, six, and 12 months. The primary outcome measures were patient safety, frequency of adverse events, repeat intervention rate, symptom severity and health-related quality-of-life scores from the validated Uterine Fibroid Symptom and Quality-of-Life Questionnaire. Secondary outcome measures were uterine volume changes over time. Mean symptom severity scores improved significantly compared with baseline at three, six, and 12 months. Mean health-related quality-of-life scores reached statistical significance over time. Mean uterine volume decreased at three six, and 12 months. There were no procedure-related repeat hospitalizations, repeat treatments or procedures related to fibroid symptoms following treatment. The study is limited by lack of randomization and control, short-term follow-up, small sample size and lack of comparison to other treatment methods. Larger multicenter studies are needed to confirm these results (Garza, 2011).

### **Professional Societies/Organizations**

#### **American Association of Gynecological Laparoscopists (AAGL):**

The AAGL published practice guidelines for the diagnosis and management of submucous leiomyomas (2012) which note with currently available evidence, embolic and ablative therapies, including leiomyoma ablation with radiofrequency electricity are not appropriate for women with submucous myomas who have current infertility or who wish to conceive in the future. The guidelines do not address embolic or ablative therapies related to submucous myomas for individuals without infertility or who do not desire future conception.

## Use Outside of the US

**Society of Obstetricians and Gynaecologists of Canada (SOGC):** the SOGC published evidenced-based guidelines for the management of uterine leiomyomas (Vilos, et al., 2015). The recommendations note that, “Of the conservative interventional treatments currently available, uterine artery embolization has the longest track record and has been shown to be effective in properly selected patients. (II-3) Newer focused energy delivery methods are promising but lack long-term data. (III)”. The newer methods included in this statement includes radiofrequency ablation of uterine fibroids.

Quality of evidence assessment:

III: Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

#### **Suprachoroidal Delivery of Pharmacological Agent (CPT Code 67299) Suprachoroidal Injection of a Pharmacologic Agent (does not include supply of medication (CPT code 0465T)**

The leading causes of blindness include those affecting the back of the eye: age-related macular degeneration, diabetic retinopathy, and uveitis. Although treatments are available, delivering drugs to the posterior regions of the eye is challenging because of architecture as well as natural barriers (Patel, 2011). Drug delivery techniques include intravitreal injections, periocular injections and intravitreal implants. Suprachoroidal drug delivery has been proposed as an alternative method to access the suprachoroid space (SCS). There have been several techniques described for injections into the SCS (Moisseiev, et al., 2016). The injection can be done using standard small-gauge needles, but this is a delicate procedure with a risk of penetration into the choroid or the vitreous cavity. Surgical cannulation may be used for drug delivery to the posterior pole, however, this is a complicated procedure and cannot be performed in-office. SCS drug delivery using microneedles is also being investigated. The micro-needles are small-gauge needles (30–33 G) and 0.7–1.0 mm in length that are only long enough to penetrate the sclera and reach the SCS. These microneedles have been demonstrated to be safe and effective in several animal studies. SCS™ microinjector (Clearside Biomedical Inc. Alpharetta, GA). is a microneedle being developed for SCS injection in humans. The device is currently undergoing two Phase 2 clinical trials with its proprietary formulation of triamcinolone acetonide (CLSTA) for the treatment of macular edema associated with noninfectious uveitis and along with aflibercept for the treatment of macular edema associated with RVO.

#### **U.S. Food and Drug Administration (FDA)**

The iScience Surgical Ophthalmic Microcannula (iScience Surgical Corporation, Redwood City, CA) is a flexible microcannula designed to allow atraumatic cannulation of spaces in the eye such as the anterior chamber and posterior segment (FDA, 2004). It received 510(k) approval on June 22, 2004 for the following indications: fluid infusion and aspiration, as well as illumination, during surgery.

SCS™ microinjector (Clearside Biomedical Inc. Alpharetta, GA) has not yet received FDA approval.

### **Literature Review**

Randomized control trial data are lacking to demonstrate the safety and effectiveness of suprachoroidal delivery of pharmacological agents for any indication, including injection of pharmacologic agents. Studies are limited by uncontrolled design and small populations.

### **Professional Societies/Organizations**

Guidelines of the American Academy of Ophthalmologists do not include suprachoroid delivery as a method for delivering drugs to the posterior regions of the eye.

### **Use Outside of the US**

### **Conjunctival Incision with Posterior Extrasceral Placement of a Pharmacological Agent (CPT Code 68399)**

Neovascular age-related macular degeneration (AMD) is associated with a rapid loss of vision due to an abnormal growth of blood vessels in the macula of the eye, leakage, and scarring (Geltzer, 2007). Treatment options for this disease are limited and there are a variety of therapies currently being investigated for neovascular AMD. Surgical implantation of steroids with antiangiogenic and anti-inflammatory properties has been proposed as a practical method of administering these agents into the eye (Geltzer, 2007). Extrasceral placement of steroids involves an incision into the orbit posterior to the limbus, through the conjunctiva. A cannula is inserted outside the sclera until the tip is near the macula, and the drug is administered. Advantages to this procedure may include a reduced risk for retinal detachment and endophthalmitis (Geltzer, 2007).

### **Literature Review**

Randomized controlled trial (RCT) data are scarce regarding the safety and effectiveness of conjunctival incision with posterior juxtascleral placement of pharmacological agents.

Geltzer et al. (2013) reported on a Cochrane review which analyzed outcomes of three RCTs involving the administration of triamcinolone acetonide versus placebo, anecortave acetate versus placebo, and anecortave acetate versus photodynamic therapy for the treatment of age-related macular degeneration. One trial found posterior juxtrascleral depot of anecortave acetate may be effective in preventing severe vision loss. Overall the assessment noted weak evidence as to the benefits and harms of steroids with antiangiogenic properties for treating neovascular AMD by posterior juxtrascleral placement of drugs.

## Automated Evacuation of Meibomian Glands (CPT Code 0207T)

The meibomian glands are located on the eyelids and are responsible for the production of sebum. Sebum prevents the tear film from evaporating too quickly from the eye's surface. Meibomian gland dysfunction leads to decreased secretion and abnormal composition of the tear film lipid layer, which in turn can lead to blockage of the glands, dry eye, and infection. Conventional treatment includes eyelid washing, use of preservative-free tears, omega-3 dietary supplementation, topical and oral antibiotics, corticosteroids, warm compresses and gentle eyelid massage. The use of an automated heated compression device has been proposed as a treatment of meibomian gland dysfunction.

## U.S. Food and Drug Administration

The LipiFlow Thermal Pulsation System (TearScience, Morrisville, NC) received FDA 510(k) clearance in July, 2011. This system is intended to be used by a physician in an in-office procedure. The FDA approval indicates "The LipiFlow Thermal Pulsation System is intended for the application of localized heat and pressure therapy in adult patients with chronic cystic conditions of the eyelids, including meiboman gland dysfunction (MGD) also known as evaporative dry eye or lipid deficiency dry eye."

## Literature Review

Blackie, et al (2017) conducted a prospective, multicenter, open-label clinical trial that included 200 subjects (400 eyes) who were randomized to a single VTP treatment (treatment group) or twice-daily, 3-month, conventional warm compress and eyelid hygiene therapy (control group). Control group subjects received crossover VTP treatment at 3 months (crossover group). Effectiveness measures of meibomian gland secretion (MGS) and dry eye symptoms were evaluated at baseline and one, three, six, nine and 12 months. Subjects with inadequate symptom relief could receive additional meibomian gland dysfunction therapy after 3 (treatment group) and 6 months (crossover group). At three months, the treatment group had greater mean improvement in MGS ( $P<0.0001$ ) and dry eye symptoms ( $P=0.0068$ ), compared to controls. At 12 months, 86% of the treatment group had received only one VTP treatment, and sustained a mean improvement in MGS from  $6.4\pm3.7$  (baseline) to  $17.3\pm9.1$  ( $P<0.0001$ ) and dry eye symptoms from  $44.1\pm20.4$  to  $21.6\pm21.3$  ( $P<0.0001$ ); 89% of the crossover group had received only one VTP treatment with sustained mean improvement in MGS from  $6.3\pm3.6$  to  $18.4\pm11.1$  ( $P<0.0001$ ) and dry eye symptoms from  $49.1\pm21.0$  to  $24.0\pm23.2$  ( $P<0.0001$ ). Greater mean improvement in MGS was associated with less severe baseline MGS ( $P=0.0017$ ) and shorter duration of time between diagnosis and treatment ( $P=0.0378$ ). The authors concluded that a single VTP treatment can deliver a sustained mean improvement in meibomian gland function and mean reduction in dry eye symptoms, over 12 months.

To compare the effectiveness of a single LipiFlow treatment with combined lid warming and massage in patients with meibomian gland dysfunction (MGD), Finis et al. (2014) published results of a prospective, randomized, crossover, observer-masked clinical trial involving 40 subjects. Subjects were randomized to receive either a single LipiFlow treatment (LipiFlow group) or to perform standardized, twice-daily combined lid warming and massage (lid margin hygiene or control group) for three months. The primary outcome measure was improvement of subjective symptoms, as assessed by the Ocular Surface Disease Index (OSDI) scores. Secondary outcome measures included improvement of TFBUT, decreased tear osmolality, increased LLT, and increased number of expressible meibomian glands. A total of 31 subjects completed the study. A total of 31 subjects completed the 3-month follow-up. At 1 and 3 months, patients in the LipiFlow treatment group had a significant reduction in Ocular Surface Disease Index (OSDI) scores compared with those in the lid-margin hygiene group ( $p < .01$ ). Both treatments produced a significant improvement in expressible meibomian glands compared to the baseline parameters, but no significant difference was noted between the two groups. The other investigated objective parameters did not show a significant difference. The authors note while results of this small study suggest that a single LipiFlow treatment is as least as effective as a 3-month, twice-daily lid margin hygiene regimen for MGD, the study was observer-masked only, and a placebo effect may have confounded any improvements in subjective symptoms and other parameters in both groups. Study limitations include non-blinded design and small study size. Larger, blinded randomized clinical trials are required to determine impact on health outcomes.

Lane et al. (2012) conducted a study examining the safety and effectiveness of the LipiFlow System compared with the iHeat Warm Compress (WC) for adults with meibomian gland dysfunction. This was a prospective open-label, randomized, crossover multicenter clinical trial. One hundred thirty-nine subjects were randomized between LipiFlow ( $n=69$ ) and WC control ( $n=70$ ). Subjects in the LipiFlow group received a 12-minute LipiFlow treatment and were reexamined at one day, two weeks and four weeks. Control subjects received a five-minute iHeat treatment with instructions to perform the same treatment daily for two weeks. At two weeks, they crossed over and received the LipiFlow treatment. LipiFlow resulted in significant improvement in meibomian gland secretion at two and four weeks ( $p < 0.05$ ). There was no change in meibomian gland secretion in the control group. Limitations to the study were the small population size. Results replicated in larger RCTs are required to demonstrate the ability to apply outcomes to the general population.

Mitra et al. (2005) reported results of a prospective, controlled, observer masked, single intervention trial in which 24 normal subjects were randomized into three groups: Group I: 10 minutes with the activated device, Group II: 10 minutes with the inactivated device, Group III: no intervention. The lipid layer thickness of each subject was measured prior and subsequent to the 10-minute period. A statistically significant increase in lipid layer thickness was seen in 87% of subjects in Group I ( $p < 0.001$ , left eye,  $p < 0.003$ , right eye.). Seventy-five percent of subjects experienced subjective improvement in ocular comfort. The authors note that meibomian therapy using this novel device results in increased lipid layer thickness. A limitation of this study was the small study population.

Korb et al. (2011) reported on a study attempting to determine the pressure required to express the first non-liquid material from nonfunctional lower lid meibomian glands, the pressure required to evacuate all of the expressible material from the glands, and the level of pain associated with these actions. Custom instrumentation was applied to the lower lid, exerting pressures from 1.0 to 150.0 pounds per square inch (psi). Pressure was monitored throughout the procedure as was pain level. The pressure required to obtain the first non-liquid material ranged between 5-40 pounds per square inch. Pain was the limiting factor for this treatment. Only 7% of the patients could tolerate the pressure necessary to administer complete expression of the non-liquid material.

### **Professional Societies/Organizations**

**American Academy of Ophthalmology (AAO) (2013):** the AAO preferred practice patterns for dry eye syndrome do not include automated heated compression device has been proposed as a treatment of meibomian gland dysfunction.

### **Use Outside of the US**

## **Insertion of Ocular Telescope Prosthesis Including Crystalline Lens (CPT Codes 0308T, HCPCS Code C1840)**

The prosthetic intraocular telescope system is intended for the treatment of central vision loss (bilateral central scotomas) due to age-related macular degeneration (AMD). The device projects an image onto the part of the retina which is still healthy and can still see images. The device not intended to cure AMD, however it has the potential to improve quality of life and daily functioning for patients with end-stage AMD. The implantation inside the eye allows the patient to use natural eye movements to see, rather than head movements, which are required when using external magnification devices for AMD-related low vision.

**U.S. Food and Drug Administration (FDA):** The Implantable Miniature Telescope™ (VisionCare Ophthalmic Technologies, Saratoga, CA) received FDA premarket approval in July 2010. According to the FDA, this device is an implantable device which, when combined with the optics of the cornea, constitutes a telephoto system for improvement of visual acuity in patients with severe to profound vision impairment due to bilateral, end-stage, age-related macular degeneration (AMD). The implantable miniature telescope (IMT) is surgically implanted in the capsular bag and is held in position by haptic loops. The intraocular telescope is available in two models: Wide Angle (WA) 2.2X and Wide Angle (WA) 2.7X. Both models are indicated for monocular implant. The implanted eye provides central vision, while the fellow eye continues to be used for peripheral vision.

The initial FDA approval noted the device is intended to improve vision in patients 75 years of age or older with stable, severe to profound vision impairment caused by end-stage age-related macular degeneration. The device is indicated for (FDA, 2010):

- monocular implantation to improve vision in patients greater than or equal to 75 years of age with stable, severe to profound vision impairment (best corrected distance visual acuity 20/160 to 20/800) caused by bilateral central scotomas associated with endstage age-related macular degeneration.
- Patients must:
  - have retinal findings of geographic atrophy or disciform scar with foveal involvement, as determined by fluorescein angiography;
  - have evidence of visually significant cataract (> grade 2)

- agree to undergo presurgery training and assessment (typically 2 to 4 sessions) with low vision specialists (optometrist or occupational therapist) in the use of an external telescope sufficient for patient assessment and for the patient to make an informed decision;
- achieve at least a 5-letter improvement on the ETDRS chart with an external telescope;
- have adequate peripheral vision in the eye not scheduled for surgery; and 6) agree to participate in postoperative visual training with a low vision specialist.

In October 2014, the FDA expanded the age limit for Implantable Miniature Telescope (IMT) to 65 years of age or older. The supplement also included revisions to the professional and patient labeling with updated data based on the results out to eight years post IMT implantation; to revise the acceptance of risk and informed decision agreement; and to the professional and patient labeling to emphasize that the longer the IMT is in the eye, the greater the potential risk of developing vision-impairing corneal edema which may lead to the need for corneal transplant and possible telescope removal.

As part of the initial approval, there was a requirement for extended follow-up of the premarket cohort population. According to the FDA, this continued follow-up of individuals in the long-term follow-up cohort (5 years postoperatively) will be conducted to provide additional long-term (up to eight years) safety data. The FDA also requires a multicenter, prospective, open label, single group assignment cohort study for safety. The study is required to consecutively will enroll 770 presurgical subjects aged 75 years and older with severe to profound vision impairment caused by end-stage age-related macular degeneration and a cataract. The subjects enrolled and undergoing implantation of the IMT will be followed for a total of five years with approximately six follow-up visits during the first year followed by annual visits thereafter for the next four years (FDA, 2010).

According to the FDA Summary Of Safety And Effectiveness implantation of the device is contraindicated in patients (FDA, 2010):

- Stargardt's macular dystrophy
- central anterior chamber depth (ACD) <3.0 mm; measurement of the ACD should be taken from the posterior surface of the cornea (endothelium) to the anterior surface of the crystalline lens.
- presence of corneal guttata.
- minimum age and endothelial cell density requirements are not met
- with cognitive impairment that would interfere with the ability to understand and complete the Acceptance of Risk and Informed Decision Agreement or prevent proper visual training/rehabilitation with the device
- who have evidence of active choroidal neovascularization (CNV) on fluorescein angiography or treatment for CNV within the past six months
- with any ophthalmic pathology that compromises the patient's peripheral vision in the fellow eye
- with previous intraocular or cornea surgery of any kind in the operative eye, including any type of surgery for either refractive or therapeutic purposes
- who have prior or expected ophthalmic related surgery within 30 days preceding intraocular telescope implantation
- with a history of steroid-responsive rise in intraocular pressure (IOP), uncontrolled glaucoma, or preoperative IOP >22 mm Hg, while on maximum medication
- with known sensitivity to post-operative medications
- who have a history of eye rubbing or an ocular condition that predisposes them to eye rubbing
- in whom the planned operative eye has:
  - myopia > 6.0 D
  - hyperopia > 4.0 D
  - axial length < 21 mm
  - a narrow angle, i.e., < Schaffer grade 2
  - cornea stromal or endothelial dystrophies, including guttata
  - inflammatory ocular disease
  - zonular weakness/instability of crystalline lens, or pseudoexfoliation
  - diabetic retinopathy

- untreated retinal tears
- retinal vascular disease
- optic nerve disease
- a history of retinal detachment
- intraocular tumor
- retinitis pigmentosa.
- in eyes in which both haptics cannot be placed within the capsular bag during surgery, the intraocular telescope should be removed and replaced with a conventional intraocular lens (IOL); sulcus fixation of either one or both haptics increases the risk of severe endothelial cell loss and corneal transplant

## Literature Review

Hudson et al. (2006) reported on a prospective, open-label, multicenter clinical trial (IMT-002 clinical trial) with fellow eye controls. The trial included 217 patients with AMD and moderate to profound bilateral central visual acuity loss (20/80-20/800) resulting from bilateral untreatable geographic atrophy, disciform scars. A visual prosthetic device (implantable telescope), designed to enlarge retinal images of the central visual field, was implanted monocularly in the capsular bag after lens extraction. Fellow eyes were not implanted to provide peripheral vision and served as controls. Study patients participated in six visual rehabilitation visits after surgery. At one year, 67% of implanted eyes achieved a 3-line or more improvement in best-corrected distance visual acuity (BCDVA) versus 13% of fellow eye controls ( $P < 0.0001$ ). Fifty-three percent of implanted eyes achieved a 3-line or more improvement in both BCDVA and BCNVA versus 10% of fellow eyes ( $P < 0.0001$ ). Mean BCDVA and best-corrected near visual acuity (BCNVA) improved 3.5 lines and 3.2 lines, respectively, in implanted eyes versus 0.8 lines and 1.8 lines, respectively, in fellow eyes ( $P < 0.0001$ ). Eleven eyes did not receive the device because of an aborted procedure. Endothelial cell density was reduced by 20% at three months and 25% at one year. The decrease in Endothelial cell density (ECD) was correlated with postsurgical edema ( $P < 0.0001$ ) with no evidence that endothelial cell loss is accelerated by ongoing endothelial trauma after implantation, the authors concluded that the device can improve visual acuity and quality of life in patients with moderate to profound visual impairment caused by bilateral, end-stage AMD.

Hudson et al. (2008) reported on two year results of the above study. The main outcome measures included BCVA change from baseline, endothelial cell density (ECD) and morphometry, and incidence of complications. At two years, data from 174 (92.6%) of 188 available patients were analyzed with findings that overall, 103 (59.5%) of 173 telescope-implanted eyes gained three lines or more (doubling of visual angle) of BCVA compared with 18 (10.3%) of 174 fellow control eyes ( $P < .0001$ ). Mean BCVA improved 3.6 lines (standard deviation [SD], 1.9 lines) and 2.8 lines (SD, 2.3 lines) from baseline in eyes with the 3X and 2.2X device models, respectively. Mean ECD stabilized through two years, with 2.4% mean cell loss occurring from one to two years. There was no significant change in coefficient of variation or percentage of hexagonal endothelial cells from within six months to two years after surgery. The most common complication found to be inflammatory deposits. The authors concluded that long-term results of this telescope prosthesis indicate the substantial BCVA improvement at one year is maintained at two years with the key indicators of corneal health demonstrating ECD change that reflects remodeling of the endothelium associated with the implantation procedure and no that there is no evidence of any ongoing endothelial trauma.

Boyer et al. (2015) reported on the long-term results (60 months) of implantable miniature telescope (IMT) in patients with bilateral, end-stage, age-related macular degeneration (AMD) (studies above Hudson, et al., 2006; Hudson et al., 2008). A subgroup analysis was performed with stratification for age (patient age 65 to <75 years [group 1; n=70] and patient age  $\geq 75$  years [group 2; n=127]), with a comparative evaluation of change in best-corrected distance visual acuity (BCDVA), quality of life, ocular complications from surgery, adverse events, and endothelial cell density (ECD). The mean BCDVA improvement from baseline to 60 months was  $2.41 \pm 2.69$  lines in all patients (n=76), with  $2.64 \pm 2.55$  lines in group 1 and  $2.09 \pm 2.88$  lines in group 2. The quality of life scores were significantly higher in group 1. The most common significant surgery-related ocular complications in group 1 were iritis >30 days after surgery (7/70; 10%) and persistent corneal edema (3/70; 4.3%); and in group 2 were a decrease in BCDVA in the implanted eye or IMT removal (10/127 each; 7.9%), corneal edema >30 days after surgery (9/127; 7.1%), and persistent corneal edema (6/127; 4.7%). The significant adverse events included four corneal transplants, comprising two (2.9%) in group 1 and two (1.6%) in group 2. At 60 months, one patient in group 1 (3.2%) and three patients in group 2 (9.4%) had lost  $\geq 2$  lines of vision. The IMT was removed in one (1.4%) and ten (7.9%) patients in group 1 and group 2, respectively. Mean ECD loss was 20% at 3 months.

Chronic loss was 3% per year. ECD loss was less in group 1 than in group 2 (35% versus 40%, respectively) at 60 months. These long-term results indicate substantial retention of improvement in BDCVA. The chronic ECD loss appears consistent with that reported for conventional intraocular lenses. The results indicate that younger patients retained more vision than their older counterparts with fewer adverse events.

### **Use Outside of the US**

National Institute for Health and Care Excellence (NICE) published guidelines for miniature lens system implantation for advanced age-related macular degeneration. The guidelines note (NICE, 2016) that, "Evidence on the efficacy of miniature lens system implantation for advanced age-related macular degeneration (AMD) shows that the procedure can improve both vision and quality of life in the short term. Data on short-term safety are available for limited numbers of patients. There is currently insufficient long-term evidence on both efficacy and safety. Therefore this procedure should only be used with special arrangements for clinical governance, consent and audit or research."

### **Quantitative Pupillometry (CPT Code 0341T)**

Pupil reactivity and sensitivity may indicate neurological issues or worsening of neurological status. Current practice is to use a penlight to observe the pupillary light reflex which is a subjective measurement. Several quantitative pupillometer devices are available, although their use is primarily restricted to the research setting (Couret, et al., 2016). The stimulation and subsequent measurement of pupil reactivity by a hand held infrared camera and use of a digital device and data processor to calculate measurements has been proposed for a number of indications including the evaluation of autonomic function, response to pain, drug metabolism, sleep disorders, and various psychological indications and has been use in the research setting. A pupillometer is made of three components: the light source to stimulate the pupil, an image capturing device capable of taking measurements of the pupil in real-time, and a data processor that performs the calculations using the measurements. The device is held in the patient's visual field, the data is interpreted, and a report is generated.

### **Literature Review**

High level, randomized and controlled data are lacking regarding the effectiveness of this device in the published, peer viewed scientific literature.

Couret et al. (2016) reported on study that compared automated quantitative pupillometry with the standard clinical pupillary examination currently used for brain-injured patients. Repetitive measurements were made in 200 healthy volunteers providing a total of 400 paired (alternative right eye, left eye) measurements under a wide variety of ambient light condition with the NeuroLight Algiscan pupillometer and then a prospective, observational, double-blinded study was conducted in two neurocritical care units. In 200 healthy volunteers, intra-class correlation coefficient for maximum resting pupil size was 0.95 (IC: 0.93-0.97) and for minimum pupil size after light stimulation 0.87 (0.83–0.89). It was found 3-pupil asymmetry ( $\geq 1$  mm) in these volunteers (1.5 % of the population) with a clear pupil asymmetry during clinical inspection. The mean pupil light reactivity was  $40 \pm 7$  %. In 59 patients, 406 pupillary measurements were prospectively performed. Concordance between measurements for pupil size collected using the pupillometer, versus subjective assessment, was poor (Spearman's rho = 0.75, IC: 0.70-0.79;  $P < 0.001$ ). A global rate of discordance of 18 % (72/406) was found between the two techniques when assessing the pupillary light reflex. For measurements with small pupils (diameters  $< 2$  mm) the error rate was 39 % (24/61). The results demonstrated that pupillary evaluations obtained subjectively at the patient's bedside were inaccurate compared with those obtained with an automatic quantitative pupillometer device. The authors concluded that the standard practice in pupillary monitoring yields inaccurate data, that automated quantitative pupillometry is a appears to be a more reliable method with which to collect pupillary measurements at the bedside; however, the impact of a pupillometer use on patients' outcome has to be demonstrated in further prospective studies.

In a cross-sectional cohort study Kantor et al. (2014) assessed the association between postoperative pain (NRS) and pupillary diameter or pupillary light reflex amplitude (PLRA) in 145 Post Anesthesia Care Unit (PACU) patients after routine anesthetic care. Sedation, hemodynamic, pupillary and pain assessments were performed in each patient after their arrival in the PACU or before morphine titration. In patients receiving morphine titration, a second assessment was performed after titration. Sedation was assessed using the modified Observer's Assessment of Alertness/Sedation (OAAS) scale. Hemodynamic assessment consisted of non-invasive systolic and diastolic blood pressure and heart rate. Pupillary assessment was performed with an infrared portable dynamic videopupillometer. Mean numerical rating score (NRS) for pain as assessed by study participants was 4.7, and was more than four in 79 patients (55%). No statistically significant association was observed between NRS and pupillary diameter ( $p=0.54$ ). Twenty-seven patients (19%) received morphine titration with significant decreases in NRS, pupillary diameter and PLRA afterwards. No association was observed between NRS changes and pupillary diameter or PLRA changes. The authors concluded acute postoperative pain is not associated with pupillary diameter or PLRA. Further high quality randomized clinical trial data is required to demonstrate the impact of pupillometry as a means to assess pain in the PACU.

Bremner et al. (2006) reported results of a prospective study of involving the use of light reflex pupillography in 150 consecutive patients with symptomatic generalized autonomic failure. Inclusion criteria was heterogeneous with a variety of indications represented including amyloidosis, multiple system atrophy, pure autonomic failure, diabetes mellitus, hereditary neuropathies, and paraneoplastic syndromes. Infra-red video pupillography was used to measure resting pupil diameters in light and dark, the light reflex response, the miosis associated with an accommodative effort, and responses to topical administration of various pharmacological agents. No significant correlation between the type of pupil abnormality and the predominant type of systemic autonomic deficit was seen in most conditions. The authors note "Although there does appear to be some weak correspondence between our pupillographic findings and the results of autonomic function tests, a  $\chi^2$  test suggests that this association could have arisen by chance ( $p=0.072$ )."

### **Retinal prosthesis system (Device evaluation, interrogation, and initial programming of intra-ocular retinal electrode array) (CPT codes 0100T, 0472T, 0473T, C1841, C1842)**

Retinitis pigmentosa (RP) comprises a complex group of inherited dystrophies characterized by progressive degeneration and dysfunction of the retina, primarily affecting photoreceptor and pigment epithelial function. The clinical manifestations of RP include night blindness, loss of peripheral vision from progressive loss of photoreceptors, and variably loss of central vision due to cataracts and macular edema (Garg [UpToDate], 2017). The Argus II Retinal Prosthesis System (Argus II) (Second Sight Medical Products, Inc. Sylmar, CA) is intended to provide electrical stimulation of the retina to elicit visual perception in blind individuals with severe to profound retinitis pigmentosa. The implant is an epiretinal prosthesis that is surgically implanted in and on the eye that includes an antenna, an electronics case, and an electrode array. The external equipment includes glasses, a video processing unit (VPU) and a cable.

**U.S. Food and Drug Administration (FDA):** The Argus II Retinal Prosthesis System received a Humanitarian Device Exemption (HDE) from the FDA in February 2013. This device is indicated for use in patients with severe to profound retinitis pigmentosa who meet the following criteria:

- Adults, age 25 years or older.
- Bare light or no light perception in both eyes. (If the patient has no residual light perception, then evidence of intact inner layer retina function must be confirmed.)
- Previous history of useful form vision.
- Aphakic or pseudophakic. (If the patient is phakic prior to implant, the natural lens will be removed during the implant procedure.)
- Patients who are willing and able to receive the recommended post-implant clinical follow-up, device fitting, and visual rehabilitation.

## Literature Review

Agency for Healthcare Research and Quality (AHRQ) published a technology assessment for retinal prostheses systems (RPS) in the Medicare population (Fontanarosa, et al., 2016). The review included 30 publications of 11 RPS studies. The report notes that, "Although some patients clearly experienced improved visual acuity, visual field, and visual function, the percentages varied greatly among studies of Moderate to High risk of bias. Thus, evidence is insufficient to estimate the proportion of patients who will benefit from an RPS." The report concluded that some patients clearly benefit from implantation with an RPS, but determining who those patients are is still a challenge. Future studies of retinal prostheses devices should make an effort to report valid and reliable measures of important outcomes, especially day-to-day function and quality of life (QoL).

Dagnelie et al. (2017) conducted a study with the objective to test 28 Argus II subjects, all profoundly blind on three real-world functional vision tasks. Subjects were tested on the three real-world functional vision tasks: Sock Sorting, Sidewalk Tracking and Walking Direction Discrimination task. The mean percentage correct OFF versus ON for the Sock Sorting task was found to be significantly different for both testing conditions (t-test,  $P < 0.01$ ). On the Sidewalk Tracking task, subjects performed significantly better with the system ON than they did with the system OFF (t-test,  $P < 0.05$ ). Eighteen (18) of 27 subjects (67%) performed above chance with the system ON, and 6 (22%) did so with system OFF on the Walking Direction Discrimination task. The authors concluded that Argus II subjects performed better on all three tasks with their systems ON than they did with their systems OFF. The study is limited by the small number of subjects and needs to be confirmed in a larger study.

Da Cruz conducted a prospective, multicenter, single-arm, clinical trial of 30 subjects in 10 centers in US and Europe to study the long-term safety and efficacy of the Argus II System in patients with bare or no light perception due to end-stage RP. Within-patient controls included the non-implanted fellow eye and patients' native residual vision compared to their vision when using the System. The primary outcome measures were safety (the number, seriousness, and relatedness of adverse events) and visual function, as measured by three computer-based, objective tests. Secondary measures included functional vision performance on objectively-

scored real-world tasks. Twenty-four out of 30 patients remained implanted with functioning Argus II Systems at 5 years post-implant. Only one additional serious adverse event was experienced since the three-year time point. Patients performed better with the System ON than OFF on all visual function tests and functional vision tasks. The authors concluded that the five-year results of the Argus II trial support the long-term safety profile and benefit of the Argus II System for patients blind from RP.

### **Professional Societies/Organizations**

Professional society guidelines are lacking regarding intra-ocular retinal electrode array for treatment of retinitis pigmentosa.

### **Use Outside of the US**

**Health Quality Ontario:** this organization published a health technology assessment for retinal prosthesis system for advanced retinitis pigmentosa (2017). The recommendation of the assessment notes, "The Ontario Health Technology Advisory Committee recommends publicly funding the Argus II retinal prosthesis system for advanced retinitis pigmentosa." The committee determined that the Argus II system has demonstrated clinical effectiveness in restoring partial functional vision for patients with advanced retinitis pigmentosa. The Ontario Health Technology Advisory Committee took into account value for money, as well as the lived experience of people with retinitis pigmentosa and noted that the Argus II system offers the possibility of quality-of-life improvements in a population for whom there is no other treatment option.

**National Institute for Health and Care Excellence (NICE):** NICE published interventional procedure guidance for insertion of epiretinal prosthesis and insertion of a subretinal prosthesis system for retinitis pigmentosa (NICE, 2015). The guidance includes these recommendations:

Subretinal prosthesis system:

- Current evidence on the safety and efficacy of insertion of a subretinal prosthesis system for retinitis pigmentosa is limited in quality and quantity. Therefore, this procedure should only be used in the context of research.
- NICE encourages further research on this procedure. Outcomes should include the impact on quality of life and activities of day-to-day living, and durability of implants.

Epiretinal prosthesis:

- Current evidence on the safety and efficacy of insertion of epiretinal prosthesis for retinitis pigmentosa is limited in quality and quantity. Therefore, this procedure should only be used in the context of research.
- NICE encourages further research on this technology. Outcomes should include the impact on quality of life and activities of day-to-day living, and durability of implants.

## **Oncology**

### **Tumor Treatment Fields Therapy (e.g., Optune™) (HCPCS Codes A4555, E0766)**

Electric tumor treatment fields (TTF) therapy, also known as alternating electric field therapy, has been proposed for the treatment of recurrent glioblastoma multiforme (GBM). Inferred mechanism of action is disruption of the rapid cell division exhibited by cancer cells by alternating electrical currents applied to the brain through electrically insulated surface transducer arrays which are placed on the patient's shaved scalp. The fields alter the tumor cell polarity at an intermediate frequency. The frequency used for a particular treatment is specific to the cell type being treated (NovoCure, 2014).

At this time, Optune™ (formerly the NovoTTF-100A System) (Novocure, Portsmouth, NH) is the only TTF device that has received FDA approval electric tumor fields therapy. This system is a wearable, non-invasive, portable battery or power-supply operated device designed for continuous use throughout the day or night. It produces continuous TTF treatment at 100-200kHz. TTF are applied to two pairs of insulated electrode arrays in an alternating fashion. The electrodes are placed on the scalp over a layer of adhesive hydrogel which is held in place by adhesive strips. The scalp must be re-shaved to maintain optimal contact between the electrode and

the skin. Gel under the electrodes requires replacement every three-four days. The treatment period is for a minimum of four weeks.

### **U.S. Food and Drug Administration (FDA)**

The NovoTTF-100A System (Portsmouth, NH) was granted premarket approval (PMA) by the FDA in April, 2011. This device is indicated for treatment of adult patients who are 22 years of age or older who have histologically-confirmed glioblastoma multiforme (GBM), following histologically-or radiologically confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted. The pre-market approval requires a post market nonrandomized, unblinded, concurrent control study to be undertaken using the NovoTTF-100A system in patients with recurrent GBM (FDA, 2011).

In October 2015, the FDA approved an expanded indication for the Optune device to treat patients with newly-diagnosed glioblastoma multiforme (GBM), an aggressive form of brain cancer. It is given along with the chemotherapy drug temozolomide (TMZ) following standard treatments that include surgery, and radiation therapy and chemotherapy used together.

### **Literature Review**

Stupp et al. (2015) reported on an interim analysis of a multicenter, open-label, randomized phase 3 trial designed to test the efficacy and safety of TTFields in combination with temozolomide for treatment of glioblastoma after initial treatment with chemoradiation. The study included 210 patients randomized to TTFields plus temozolomide and 105 patients randomized to temozolomide alone, and conducted at a median follow-up of 38 months. Results included that median progression-free survival in the intent-to-treat population was 7.1 months (95%CI, 5.9-8.2 months) in the TTFields plus temozolomide group and 4.0 months (95%CI, 3.3-5.2 months) in the temozolomide alone group (hazard ratio [HR], 0.62 [98.7%CI, 0.43-0.89];  $P=.001$ ). Median overall survival in the per-protocol population was 20.5 months (95%CI, 16.7-25.0 months) in the TTFields plus temozolomide group ( $n=196$ ) and 15.6 months (95%CI, 13.3-19.1 months) in the temozolomide alone group ( $n=84$ ) (HR, 0.64 [99.4%CI, 0.42-0.98];  $P=.004$ ). The authors concluded that in this analysis of patient with glioblastoma who had completed standard chemoradiation therapy, the addition of TTFields to maintenance temozolomide chemotherapy significantly prolonged progression-free and overall survival.

Stupp et al. (2017) reported on the final analysis randomized, trial noted above (Stupp, et al., 2015) of all 695 patients with median follow-up of 40 months and minimum follow-up of 24 months. Patients were randomized 2:1 to TTFields plus maintenance temozolomide chemotherapy ( $n = 466$ ) or temozolomide alone ( $n = 229$ ). The TTFields, consisting of low-intensity, 200 kHz frequency, alternating electric fields, was delivered ( $\geq 18$  hours/d) via 4 transducer arrays on the shaved scalp and connected to a portable device. Temozolomide was administered to both groups for 5 days per 28-day cycle (6-12 cycles). Progression-free survival (tested at  $\alpha = .046$ ). The secondary end point was overall survival (tested hierarchically at  $\alpha = .048$ ). Analyses were performed for the intent-to-treat population. Of the 695 patients 637 (92%) completed the trial. Median progression-free survival from randomization was 6.7 months in the TTFields-temozolomide group and 4.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.52-0.76;  $P < .001$ ). Median overall survival was 20.9 months in the TTFields-temozolomide group vs 16.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ). Systemic adverse event frequency was 48% in the TTFields-temozolomide group and 44% in the temozolomide-alone group. Mild to moderate skin toxicity underneath the transducer arrays occurred in 52% of patients who received TTFields-temozolomide compared to none in patients who received temozolomide alone.

Hayes published a directory report regarding Tumor Treating Fields (TTF) (Hayes, March 2016; 2018). The review concluded that although clinical trials have shown that Novocure is at least comparable with chemotherapy, the body of literature is small and individual studies are subject to serious limitations, including lack of a control or comparator group, high loss to follow-up, and lack of statistical comparisons. Additional evidence including randomized, controlled trials and cohort studies of sufficient size and design are needed to further investigate the safety and efficacy of Novocure in patients with recurrent and newly diagnosed glioblastoma and other cancers.

Data regarding the safety and effectiveness for TTF are limited in the published, peer-reviewed scientific literature and consist of several prospective studies and a randomized clinical trial (RCT) involving a total of 273 patients (Stupp, 2012; Kirson, 2009; Salzbeg, 2008; Kirson, 2007). In the prospective phase III RCT, Stupp et al. (2012) reported results of 237 individuals with recurrent GBM. Participants were randomized to TTF (n=120) versus physician's choice of chemotherapy (n=117). The study failed to reach its primary end-point of improved survival compared to active chemotherapy. Neither overall survival nor progression-free survival were significantly improved at six months in the group randomized to TTF versus chemotherapy (p=0.23 and 0.13, respectively). The authors noted that responses were more frequent in the group treated with TTF but this was not significant (p=0.19). Quality of life measurement favored TTF over chemotherapy for emotional and cognitive functioning; no significant difference was noted for global health and social functioning. Physical functioning favored the chemotherapy arm. TTF-related adverse events were mild (14%) to moderate (2%), usually involving skin rash beneath the transducer arrays. Severe adverse events occurred in 6% and 16% (p = 0.022) of patients treated with TTF and chemotherapy, respectively. Results do not demonstrate improved OS or PFS with TTF compared to active chemotherapy.

#### **NovoTAL™ (CPT code 64999)**

NovoTAL (Novocure, Portsmouth, NH) is software that may be used for treatment planning before the Optune treatment. According to vendor's website, NovoTAL is optional software that a physician can purchase and create individualized treatment maps for patients starting Optune. It is performed in-office. The physicians are required to complete training and certification in order to use the NovoTAL System. The Optune device is available preset from Novocure. The device is preset to deliver TTFields at a frequency of 200 kHz and is operated by the patient independently. It is monitored periodically by device specialists, who are available 24/7 to provide technical support to the patient, their family and physician (Trusheim, et al., 2017). The published literature does not indicate that the use of the software for treatment planning with Novotal is superior to using Optune with preset settings or that it improves clinical outcomes.

#### **Literature Review—NovoTAL**

Wenger et al. (2016) reported on a study with a human head model generated from MRI images of a healthy subject to investigate tumors of different size, shape, and location and the effect of varying transducer layouts on Tumor Treating Fields (TTF) distribution in an anisotropic model. Four different virtual tumors were placed at separate locations. The transducer arrays were modeled to mimic the TTF-delivering commercial device. For each tumor location, varying array layouts were tested. The finite element method was used to calculate the electric field distribution, taking into account tissue heterogeneity and anisotropy. In all tumors, the average electric field induced by either of the two perpendicular array layouts exceeded the 1-V/cm therapeutic threshold value for TTF effectiveness. Field strength within a tumor did not correlate with its size and shape but was higher in more superficial tumors. Additionally, it always increased when the array was adapted to the tumor's location. Compared with a default layout, the largest increase in field strength was 184%, and the highest average field strength induced in a tumor was 2.21 V/cm. The authors concluded that the result adapting transducer array layouts to specific tumor locations was highly beneficial, because it led to substantial increases in the induced field strength within the tumor and better TTF coverage in the affected areas.

Connelly et al. (2016) reported on a case series of eight patients where treating physician has utilized non-contrast enhancement and advanced imaging to inform tumor treatment fields (TTF) treatment planning based on a clinical evaluation of where a patient is believed to have active tumor. All patients presented with gliomas (grades 2–4). Each patient had previously received standard therapy including surgery, radiation therapy and/or chemotherapy prior to initiation of TTF and the majority had progressed on prior therapy. A standard pre- and postcontrast MRI scan was acquired and used for TTF treatment planning. The authors concluded that the case series details important approaches for integrating clinical considerations, nonmeasurable disease and advanced imaging into the treatment planning workflow for TTF. The author noted that as TTF become integrated into standard care pathways for glioblastoma, the case series demonstrates that treatment planning beyond the extent of contrast enhancement is clinically feasible and should be prospectively compared to standard treatment planning in a clinical trial setting, in order to determine the impact on patient outcomes.

Chaudry et al. (2015) reported on a study that evaluated performance of 14 physicians in conducting transducer array layout mapping using the NovoTAL System compared with mapping performed by the Novocure in-house clinical team. The physicians evaluated five blinded cases of recurrent glioblastoma and performed head size

and tumor location measurements using a standard Digital Imaging and Communications in Medicine reader. Concordance with Novocure measurement and intra- and inter-rater reliability were assessed using relevant correlation coefficients. The study criterion for success was a concordance correlation coefficient (CCC) >0.80. CCC for each physician versus Novocure on 20 MRI measurements was 0.96 (standard deviation, SD  $\pm$  0.03, range 0.90–1.00). Intra- and inter-rater reliability correlation coefficients were similarly high: 0.83 (SD  $\pm$  0.15, range 0.54–1.00) and 0.80 (SD  $\pm$  0.18, range 0.48–1.00), respectively. This user study has a low number of participants and while it appears that there is a high agreement between the two groups, it does not indicate that NovoTAL provides improved health outcomes compared to mapping provided by Novocure.

### Professional Societies/Organizations

**National Comprehensive Cancer Network<sup>™</sup> (NCCN<sup>™</sup>):** NCCN guideline for cancer of the central nervous system includes in the recommendation for treatment of recurrent disease, the option to consider alternating electric field therapy for recurrent disease for anaplastic oligodendroglioma, anaplastic oligoastrocytoma, anaplastic astrocytoma, and glioblastoma. Category 2B\*

The 2018 update of the NCCN guidelines includes in the recommendation for treatment of glioblastoma (with supratentorial disease), adjuvant treatment, the option of using adjuvant temozolomide and alternating electric field therapy. Category 1\*

\*NCCN Categories of Evidence and Consensus:

Category 1: Based upon high-level evidence, there is uniform NCCN consensus that the intervention is appropriate.

Category 2B: Based upon lower-level evidence, there is NCCN consensus that the intervention is appropriate (NCCNa, 2018).

### Use Outside of the US

A second generation Optune device has received placement of the CE Mark for use in the European Union.

## **Otolaryngology**

### **Automated Audiometry Devices (CPT Codes 0208T, 0209T, 0210T, 0211T, 0212T)**

Audiometers measure and characterize hearing loss by determining an individual's hearing threshold. Conventional tests utilized for assessment include the behavioral pure-tone audiogram (hearing sensitivity of single-frequency signals) and speech recognition (hearing sensitivity for spoken material). These tests require interaction between the trained technician or audiologist and the patient. Conventional audiometry tests are performed manually and interpretation of the raw data is performed by the audiologist.

The use of automated audiometry devices has been proposed as an alternative to manually operated devices. Automated units use conventional technology; however, the equipment is fully automated. Results are displayed as pass or fail/refer and do not require further interpretation by a technician or audiologist. A failure score may result in further referral to a health care professional.

### **U.S. Food and Drug Administration (FDA)**

Several automated audiometric devices have received FDA 510 (k) approval. These include, but are not limited to: the AuDX Otoacoustic Emissions Measurement System with AuDX I/O Function (Natus Medical Incorporated, Mundelein, IL) received FDA 510(k) approval as an equivalent device in December 2011. The device is indicated for use when it is necessary for a trained health care professional to measure or determine cochlear function. The device can be used for patients of all ages, from newborn infants through adults to include geriatric patients. The otoacoustic emissions test is especially indicated for use in testing individuals for whom behavioral results are deemed unreliable, such as infants, young children, and cognitively impaired adults. The Otogram™ Hearing Diagnostic System (Ototronix Diagnostics, Houston, TX, formerly marketed by Tympany, Inc., Salt Lake City, UT) received FDA 510(k) approval as an equivalent device in March 2007. The device is indicated for use by trained healthcare professionals on both adults and pediatric subjects for measurement of audiometric parameters to identify and supply to help diagnose hearing loss and ear disorders.

### **Literature Review**

Although there are a number of cohort and case series reported in the published peer-reviewed scientific literature, randomized controlled trial, meta-analysis and systematic review data are lacking. In a nonrandomized comparison study by Lancaster et al. (2008) involving screening results of 32 children using on-site and telehealth screening methods the authors report identical otoscopic and immittance results. Pure-tone results were different between on-site and telehealth screening methods for five of 32 students. Using the on-site pure-tone screening protocol as the 'gold standard' the authors report that the tele-health pure-tone screening protocol yielded four false positive responses and one false negative response. This study was limited by uncontrolled study design and small study numbers.

### **Professional Societies/Organizations**

**American Academy of Pediatrics (AAP):** The AAP (Harlor, et al., 2009) published recommendations for hearing assessment in infants and children. These recommendations include discussion of automated auditory brainstem response (ABR) test as an objective physiologic means of hearing screening. The guideline does not mention the automation of other tests.

### **Use Outside of the US**

No relevant information.

### **Transtympanic Micropressure Device for Ménière's Disease (e.g., Meniett™ Device) (HCPCS Code E2120)**

Ménière's disease (also called idiopathic endolymphatic hydrops) is a disorder of the inner ear. Although the cause is unknown, the disorder probably results from an abnormally large amount of fluid (called endolymph) collecting in the inner ear. The symptoms of Ménière's disease include episodic vertigo (i.e., a sensation of dizziness or spinning), hearing loss, tinnitus (i.e., ringing in the ears), and a sensation of fullness in the affected ear.

The use of a transtympanic micropressure device/low-pressure pulse generator (i.e., Meniett™) (Medtronic Xomed, Jacksonville, FL) has been proposed as an alternative to surgery. The device is prescribed by a physician and delivers low-frequency, low-amplitude pressure pulses within the range of 0–20 centimeter (cm) H<sub>2</sub>O to the middle ear via a close-fitting ear cuff and tympanostomy tube. Its mode of action is thought to be transmission of the pulses to the inner ear, promoting the flow of endolymph out of the cochlea, alleviating the hydrops and relieving symptoms. The tympanostomy tube is inserted under local anesthetic in the office setting. The patient then uses the device at home three times per day for approximately three minutes per session. The patient discontinues use when symptoms remit.

### **U.S. Food and Drug Administration (FDA)**

In December 1999, Pascal Medical AB (Sweden) received 510(k) approval from the FDA for the Meniett Low-Pressure Pulse Generator. In 2001, Medtronic Xomed, Inc. (Jacksonville, FL) purchased the device from Pascal Medical. The Meniett Low-Pressure Pulse Generator is classified as a Class II device and is indicated for the symptomatic treatment of Ménière's disease.

### **Literature Review**

Russo et al. (2017) conducted a randomized, double-blind, placebo-controlled, multicenter trial to evaluate the efficacy of portable Meniett low-pressure pulse generator in Meniere disease. The trial included 129 adults presenting Meniere disease not controlled by conventional medical treatment. The protocol included three phases: 1) placement of a transtympanic tube and evaluation of its effect (with patient was excluded if there was resolution of symptoms); 2) randomization: six-week treatment with Meniett or placebo device; 3) removal of the device and six-week follow-up period. The evaluation criteria were the number of vertigo episodes (at least 20 minutes with a 12-hour free interval) and the impact on daily life as assessed by self-questionnaires. Ninety-seven patients passed to the second phase of the study: 49 and 48 patients received the Meniett or placebo device, respectively. In the placebo group, the number of vertigo episodes decreased from  $4.3 \pm 0.6$  (mean  $\pm$  standard error of the mean) during the first phase to  $2.6 \pm 0.5$  after 6 weeks of treatment, and to  $1.8 \pm 0.8$  after the removal of the device. Similar results were observed in the Meniett device group:  $3.2 \pm 0.4$  episodes during the first phase,  $2.5 \pm$  after 6 weeks of Meniett device treatment, and  $1.5 \pm 0.2$  after the third phase. The authors concluded that an improvement of symptoms was evidenced in all patients, with no difference between the Meniett and the placebo device groups.

Van Sonsbeek et al. (2015) reported on a Cochrane review to assess the effects of positive pressure therapy (e.g., the Meniett device) on the symptoms of Ménière's disease or syndrome. The review included five randomized, clinical trials with 265 participants. Regarding primary outcome, control of vertigo, it was not possible to pool data due to heterogeneity in the measurement of the outcome measures. In most studies, no significant difference was found between the positive pressure therapy group and the placebo group in vertigo scores or vertigo days; one study, at low risk of bias, showed a significant difference in one measure of vertigo control in favor of positive pressure therapy. For the secondary outcomes, statistically significant results for loss

or gain of hearing were found. Hearing was 7.38 decibels better in the placebo group compared to the positive pressure therapy group mean difference (MD) (95% CI 2.51 to 12.25; two studies, 123 participants). The severity of tinnitus and perception of aural fullness were either not measured or inadequate data were provided in the included studies. For the secondary outcome functional level, it was not possible to perform a pooled analysis with one study showing less functional impairment in the positive pressure group than the placebo group; another study did not show any significant results. The authors concluded that there is no evidence, from five included studies, to show that positive pressure therapy is effective for the symptoms of Ménière's disease.

The Meniett device has been evaluated in several small clinical trials (Ahsan et al., 2015; Shojaku, et al., 2011; Dornhoffer, et al., 2008; Mattox, et al., 2008; Gates, et al., 2006; Stokroos, et al., 2006; Boudewyns, et al., 2005; Thomsen, et al., 2005; Gates, et al., 2004; Odkvist, et al., 2000) with the number of study participants ranging from 12-62 persons. Ahsan et al. (2014) reported results of a systematic literature review (eight studies) and meta-analysis (18 studies). Eight studies reported hearing evaluation and improvement in pure tone average after Meniett treatment ( $p=.0085$ ). Data could not be combined for American Academy of Otolaryngology–Head and Neck Surgery functional score due to heterogeneity. Of six studies reporting frequency of vertigo, Meniett treatment significantly reduced frequency of vertigo ( $p<.0001$ ). Limitations of the study include data derived from uncontrolled and retrospective studies, short follow-up of five months, and small numbers of study participants.

In the randomized controlled trial by Thomsen (2005), patients were evaluated for two months to obtain a baseline, after which tympanostomy tubes were placed, followed by two months without treatment to account for the effect of the tympanostomy tubes. Patients then received either the Meniett device for therapy or a sham device that was identical to the active device but did not give any pressure pulses except a slight pressure increase to 2 cm H<sub>2</sub>O for five seconds to maintain the leakage test. The authors state that the patients were unable to detect whether they were using the active or placebo device, but the basis for this statement is not discussed. Patients were evaluated at two, four, and eight weeks of use. Outcomes demonstrated significant improvement in functional level and in patient perception of vertigo in those receiving therapy with the Meniett device compared to the control group. There was a nonstatistically significant trend, toward reduced frequency of vertigo in those using the Meniett device. Study limitations include small population, exclusion of a large number of participants, and the inability to determine whether the improvement is related to placement of the tympanostomy tube itself.

Limitations which limit the ability to translate outcomes to routine use of this device include small study populations, lack of blinding and randomization in the majority of studies, and improvement in outcomes in individuals who were treated with the Meniett device as well as other interventions. Further large, randomized controlled trials are necessary to determine the effectiveness of this device to improve health outcomes.

### **Professional Societies/Organizations**

The Equilibrium Committee of the American Academy of Otolaryngology-Head and Neck Surgery published a Policy Statement on Micropressure Therapy for Ménière's disease (AAO-HNS 2008, updated 2016) noted that there is some medical evidence to support the use of micropressure therapy (such as the Meniett device) in certain cases of Ménière's disease. The therapy can be used as a second level therapy when medical treatment has failed and the device represents a largely non-surgical therapy that should be available as one of the many treatments for Ménière's disease.

### **Holtranscobalamin Testing (CPT Code 84999)**

Vitamin B12, also known as cobalamin is a water soluble vitamin important in normal neurologic functioning and the formation of red blood cells. Measurement of total serum cobalamin may be used to detect a deficiency state (i.e., <200pg/mL). Sensitivity and specificity of this test is poor in part because serum levels do not always correlate with body stores. Only a portion of cobalamin is metabolically active (i.e., transcobalamin). Transcobalamin-cobalamin complex (i.e., holotranscobalamin or holo-TC) testing has been proposed as an alternative measurement of vitamin B12 deficiency. Testing may be by radio- or enzyme immunoassay.

### **U.S. Food and Drug Administration (FDA)**

In January 2004, the HoloTC RIA device (Axis-Shield Biochemicals, ASA, San Diego, CA) was determined by the FDA to be substantially equivalent as an in-vitro diagnostic assay for quantitative measurement of cobalamin (vitamin B12) bound to the carrier protein transcobalamin in human serum or blood.

### **Literature Review**

Randomized controlled trial (RCT) data are scarce in the published peer-reviewed scientific literature regarding the effectiveness of holotranscobalamin testing for the diagnosis of vitamin B12 deficiency or for use in monitoring response to therapy. Hoey et al (2009) reported results of a systematic review which assessed the effectiveness of biomarkers: vitamin B12, methylmalonic acid and total homocysteine in determining vitamin B12 status in eight RCTs. All studies measured serum and plasma total vitamin B12. All biomarkers were found to be effective measures of altered vitamin B-12 intake in populations with low and borderline baseline vitamin B-12 status ( $p < 0.00001$ ); however, in the case of total vitamin B-12, substantial heterogeneity that could not be fully explained by subgroup analysis was observed. Insufficient data were available to determine the effectiveness of plasma holotranscobalamin, which was measured in only one RCT.

### **Use Outside of the US**

**British Committee for Standards in Hamatology (BCSH):** The BCSH (Devalia, et al., 2014) published recommendations for the diagnosis and treatment of cobalamin and folate disorders. Regarding holtranscobalamin testing, the Committee notes that serum holotranscobalamin has the potential as a first-line test, but an indeterminate grey area may still exist.

### **Multivariate Analysis of Patient Specific Findings with Quantifiable Computer Probability Assessment (CPT Code 99199)**

Quantitative pretest probability assessment or attribute matching matches an explicit clinical profile of a patient to a reference database to estimate the numeric value for the pretest probability of disease. It has been proposed that this assessment, which is available at the bedside, may aid the health care professional in making the decision to perform certain diagnostic tests.

According to Kline et al. (2010) attribute matching works by a selection process whereby a computer algorithm compares the results of a selected number of predictor variables obtained from the patient being evaluated to a library of research patients previously evaluated for a specific indication compiled from multiple hospitals. The algorithm returns from the library only the "matched" patients who share the same profile of predictor variables as the patient under consideration and reports the proportion of patients with disease in this matched sample.

The PREtestConsult ACS and PREtestConsult PE modules (BreathQuant Medical Systems, Inc., Charlotte, NC) are a software application that estimates the probability of acute coronary syndrome or pulmonary embolism in adult patients. According to information on the PREtestConsult website, clinical data are entered into the modules by means of a personal data assistant or computer.

### **Literature Review**

Randomized controlled clinical data are limited to evaluate the effectiveness and clinical utility of quantifiable computerized probability assessment. Kline et al. (2009) reported the results of a randomized clinical trial involving 400 adult patients (control group, n=185; intervention group, n=184) who were evaluated for chest pain in a single medical center emergency department. Patients had neither obvious evidence for acute coronary syndrome nor other obvious reasons for admission. After an electrocardiogram was performed clinicians were asked to give their estimate of the percentage probability that the patient would have an acute coronary syndrome-defining event in the subsequent 45 days. Randomization was performed by way of a sealed, sequentially numbered envelope that contained assignment to either the control or intervention group. A member of the research team followed the patient to determine physical disposition status from the emergency department. Patients were contacted by telephone at seven and 45 days after enrollment by a research coordinator who was unaware of group assignment. The mean of the pretest probability estimates from the clinicians was 4 (5%) compared with 4 (6%) for the computerized device estimate. Safety and efficacy endpoints for controls versus intervention patients, respectively, were as follows: (1) delayed or missed diagnosis of acute coronary syndrome: 1 of 185 versus 0 of 184, (2) hospital admission with no significant cardiovascular diagnosis: 11% versus 5%, (3) thoracic imaging imparting greater than 5 mSv radiation with a negative result: 20% versus 9%, (4) median length of stay: 11.4 hours versus 9.2 hours, (5) reported feeling "very satisfied" with clinician explanation of problem on follow-up survey: 38% versus 49%, and (6) readmitted within 7 days: 11% versus 4%. Data suggest that use of a quantitative estimate of the pretest probability of acute coronary syndrome was associated with reduced resource use.

### **Bioimpedance Spectroscopy to Measure Extracellular Fluid Differences Between Limbs (CPT Code 93702)**

Bioelectrical impedance analysis is a noninvasive technique measures the body's response to electrical current. Current flows along the path of least resistance through the body and thus follows tissues with the highest water content, allowing measurement of edema (AHRQ, 2010). Bioimpedance spectroscopy has been proposed as a tool to detect early stage lymphedema.

Lymphedema is a pathological condition resulting from an accumulation of protein-rich fluid in the interstitial space because of congenital or acquired damage to the lymphatic system. Acquired or secondary lymphedema may be caused by disease, trauma, or an iatrogenic process such as surgery or radiation (Agency for Healthcare Research and Quality [AHRQ], 2010). Lymphedema is generally staged by observation of the individual's physical condition (i.e., stage 0-3) and is typically diagnosed by clinical history and physical examination. AHRQ notes that it is difficult to detect stage 0 or subclinical lymphedema with current methods. According to a

technology assessment by AHRQ (2010) serial measurement of limb volume and or circumference are de facto gold standards for diagnosing secondary edema; however, no single method of assessment has emerged as the standard comparator for randomized clinical trials (AHRQ, 2010).

### **U.S. Food and Drug Administration (FDA)**

Impedimed L-Dex U400 ExtraCellular Fluid analyzer received FDA 510(k) approval on October 3, 2008 with approval of an expansion of indications on November 4, 2011. According to the approval summary it is "indicated for use on adult human patients, utilizing impedance ratios that are displayed as an L-Dex ratio that supports the measurement of extracellular fluid volume between the limbs and is presented to the clinician as an aid to their clinical assessment of unilateral lymphedema of the arm and leg in woman and the leg in men. The device is only indicated for patients who will have or who have had lymph nodes from the axillary and pelvic regions either removed, damaged or irradiated. The device is not intended to diagnose or predict lymphedema of the extremity."

### **Literature Review**

Erdogan et al. (2015) reported on a study of 37 patients with breast cancer who underwent bioimpedance spectroscopy to assess lymphedema. During a one-year follow-up period where investigators used bioimpedance measures, a statistically significant relationship was apparent between the incidence of lymphedema and disease characteristics, including the total number of lymph nodes and the region of radiotherapy. The authors concluded that preliminary results indicate that bioimpedance may be a reasonable method regular monitoring to detect lymphedema. The study was limited by the small subject number and the lack of randomization.

Barrio et al. (2015) reported on a prospective study that compared bioimpedance (L-Dex) and volume displacement (VD) measurements in a prospective cohort of 186 breast cancer patients at risk for lymphedema. Patients received baseline VD and L-Dex; with follow-up measurements performed at three-six months intervals for three years. At each visit, patients fitted into one of three categories: normal (normal VD and L-Dex); abnormal L-Dex (L-Dex > 10 or increase in 10 from baseline and normal VD); or lymphedema (relative arm volume difference of >10 % by VD  $\pm$  abnormal L-Dex). Change in L-Dex was plotted against change in VD; correlation was assessed using the Pearson correlation. At a median follow-up of 18.2 months, 152 patients were normal, 25 had an abnormal L-Dex, and 9 developed lymphedema without a prior L-Dex abnormality. Of the 25 abnormal L-Dex patients, four progressed to lymphedema, for a total of 13 patients with lymphedema. Evaluating all time points, 186 patients had 829 follow-up measurements. Sensitivity and specificity of L-Dex compared with VD were 75 and 93 %, respectively. There was no correlation found between change in VD and change in L-Dex at 3 months ( $r = 0.31$ ) or 6 months ( $r = 0.21$ ). The authors concluded that VD and bioimpedance demonstrated poor correlation with inconsistent overlap of measurements considered abnormal. It was found that of patients with an abnormal L-Dex, few progressed to lymphedema; with most patients with lymphedema not having a prior L-Dex abnormality. The authors noted that further studies are needed to understand the clinical significance of bioimpedance.

Hayes published a technology directory report regarding bioelectrical impedance (bioimpedance) analysis for assessment of lymphedema (Hayes, 2015; 2017). The review included 25 comparative studies, including two randomized controlled trials (RCTs) that assessed the use of bioelectrical impedance analysis (BIA) for detection of lymphedema (LE), with sample sizes of 20 to 295 patients known to have LE or at risk for developing LE. The findings of the report noted that there is insufficient evidence to make conclusive statements regarding the impact of BIA on the detection or assessment of LE. Individual studies or single groups of authors with multiple studies have found moderate to high correlation between BIA, circumferential measurements, and perometry; however, accuracy of BIA varied widely depending on reference standards. It was noted that there was only very limited evidence on clinical utility or the impact of BIA on patient management or outcomes.

Controlled clinical trial data are lacking. Published studies are primarily limited to case series and validation studies. A technology review by AHRQ (2010) notes there is consistent evidence to indicate that lymphedema can be reliably measured using circumferential measurements or volume displacement. Additionally the assessment noted that there is insufficient evidence to draw conclusions about the reliability of other measures including tonometry, ultrasound, lymphoscintigraphy, or bioimpedance. The authors reviewed 41 studies related to diagnosis of lymphedema. In one study included in the technology assessment the test of interest involved

differences in the sum of arm circumference between treated and untreated arms in persons with breast cancer. Circumferential differences to diagnose lymphedema were established at  $\geq 5\text{cm}$  and  $\geq 10\text{cm}$ . For differences of  $\geq 5\text{cm}$  versus bioimpedance, sensitivity was 35% and specificity was 89%. For a difference of  $\geq 10\text{cm}$  versus bioimpedance, sensitivity was 5% and specificity was 100%. For self-report compared to bioimpedance, sensitivity was 65%, specificity was 77%. In another included study bioimpedance was used diagnostically in 102 persons with breast cancer. The sensitivity of bioimpedance compared to limb volume was 10% and specificity was 98%. Two included studies involved bioimpedance alone. The first study found that mean and median bioimpedance measures were greater in the arms of women with lymphedema who survived breast cancer. In the other study single-frequency bioimpedance was highly correlated to bioimpedance spectroscopy ( $r=.99$ ). The authors noted the tests did not drive the choice of treatment or outcome.

### **Near-Infrared Spectroscopy Studies of Lower Extremity Wounds (CPT Code 0493T)**

Foot ulceration remains a major health problem for diabetic patients. A standard method for determining the effectiveness of various treatment methods and quantifying wound healing has not been established. Measurements vary from observer to observer and rely on changes in length, width, and depth (Weingarten, et al., 2010). Treatments can include moist wound healing protocols, offloading to reduce the pressure on the wound, active wound healing agents, and/or active therapies such as hyperbaric oxygen and/or negative pressure therapy. Near-infrared spectroscopy has been proposed as a noninvasive method of measuring the optical properties of tissue oxyhemoglobin content of lower extremity wounds beneath the skin surface to guide treatment.

Diffuse photon density wave (DPDW) methodology of near infrared spectroscopy (NIRS) can be used to measure the absolute concentrations of oxyhemoglobin and deoxyhemoglobin in tissue at depths of up to several centimeters. NIRS utilizes a detector and a dispersive element to allow the intensity at different wavelengths to be recorded. More data are needed to determine the threshold value that will distinguish healing from nonhealing wounds (Niedrauer, 2010).

In this procedure the wound is interrogated using a near-infrared spectroscopy device in up to 10 different locations. Data outputs are in the form of concentrations of oxygenated hemoglobin and total hemoglobin in the blood vessels in the wound. Comparing results on a weekly or biweekly basis, the clinician assesses wound healing progression to determine the need for changes in clinical approach.

### **Literature Review**

Randomized controlled clinical trial data are lacking in the published peer-reviewed scientific literature regarding the safety and effectiveness of near-infrared spectroscopy for the measurement of lower extremity wound healing, including its use for the transcutaneous measurement of oxyhemoglobin. Reisman et al. (2016) reported on a cohort study that examined the use of near-infrared spectroscopy (NIRS) to detect sustained hyperemia following lower extremity trauma. The study examined if NIRS may be a useful monitoring tool for acute compartment syndrome (ACS). Expected normal values for this measurement have yet to be established. The study included 25 cases with acute unilateral lower extremity fractures. NIRS measurements for hemoglobin saturated with oxygen (rSO<sub>2</sub>) were taken approximately 48 hours after surgical stabilization for each compartment bilaterally, using the contralateral (uninjured) leg as an internal control. Mean rSO<sub>2</sub> values taken 48 hours from surgical stabilization from each compartment of the patients' injured legs were significantly higher than the mean values of the contralateral legs (injured = 70, 68, 72, 70; contralateral = 55, 54, 57, 56 for anterior, lateral, deep posterior, and superficial posterior compartments, respectively;  $p < 0.0001$  for all compartments). The study was limited by the lack of randomization and small subject number.

### **MarginProbe® (CPT Code 19499)**

The MarginProbe System technology is based on the principle of radiofrequency (RF) spectroscopy. The technology relies on subjecting tissue to an electric field, and then measuring the tissue response to that field, yielding an electromagnetic signature. According to the manufacturer, the surgeon applies external fields to suspect tissue and captures minute differences in electromagnetic properties. The system compares those responses to an internal database of known signatures in healthy and cancerous tissues (Dune Medical, 2015).

#### **U. S. Food and Drug Administration**

In December 27, 2012, MarginProbe® (Dune Medical Devices Inc., Paoli, PA, formerly Farmington, MA) received PMA approval from the Food and Drug Administration (FDA). The Dune MarginProbe®™ System is an adjunctive diagnostic tool for identification of cancerous tissue at the margins ( $\leq 1\text{mm}$ ) of the main ex-vivo lumpectomy specimen following primary excision and is indicated for intraoperative use in conjunction with standard methods (such as intraoperative imaging and palpation) for patients undergoing lumpectomy for previously diagnosed breast cancer.

#### **Literature Review**

Hayes published a health technology brief regarding the MarginProbe System (Dune Medical Devices) (Hayes, 2017). The review included seven studies ( $n=42$  to 596) that evaluated the clinical validity, utility, and safety of MarginProbe for intraoperative assessment of surgical margins in patients with breast cancer. Two studies were randomized controlled trials (RCTs), 3 were nonrandomized cohort studies with historical controls, and 2 were prospective cohort studies. One study was determined to be fair quality; four poor quality; and, two of very poor quality. Across studies, the rates of re-excision were statistically significantly lower in patients managed using MarginProbe plus standard of care (SOC) methods when compared with SOC methods alone. While most studies focused on rates of re-excision in patients with positive tumor margins, a critical endpoint—local tumor recurrence—was not evaluated in any study, which precludes any conclusions regarding the impact of the device on clinical oncologic outcomes. Moderate margin-level sensitivity (range, 70% to 75.2%) and low-to-moderate specificity (range, 46.4% to 70%) implies that positive margins could be missed by the device or that healthy tissue could be unnecessarily resected. The review noted study limitations included: use of historical controls; short duration of follow-up; failure to standardize methods used preoperatively to locate nonpalpable lesions; failure to standardize surgical methods and SOC methods to assess specimen margins across study arms; and failure to assess clinically relevant oncologic outcomes such as local recurrence or cancer-free survival rates. Additional studies are needed to determine whether MarginProbe is a useful adjunct to SOC methods for intraoperative margin assessment of breast tumors.

Randomized controlled clinical trial data are limited in the published, peer-reviewed scientific literature. Data are primarily in the form of prospective case controlled and retrospective analyses.

Sebastian et al. (2015) reported on a retrospective, observational study that provided compilation of data from routine use of the device, to assess the impact of device utilization on re-excision rates on groups of consecutive patients, before and after the implementation of intraoperative use of the device during lumpectomy procedures. Historical re-excision rates for each surgeon (four surgeons in three centers) were established based on a consecutive set of patients from a time period proximal to initiation of use of the device. In total, 165 cases lumpectomy cases were performed. Positive margins resulted in additional re-excision procedures in 9.7% (16/165) of the cases. The corresponding historical set from 2012 and 2013 consisted of 186 lumpectomy cases, in which additional re-excision procedures were performed in 25.8% (48/186) of the cases. The reduction in the rate of re-excision procedures was significant 62% ( $P < 0.0001$ ). This study is limited by the retrospective nature of the study and small sample size.

Schnabel et al. (2014) published results of a randomized prospective clinical trial evaluating lumpectomy margin assessment with the use of MarginProbe in addition to standard methods in 596 patients with nonpalpable breast malignancies. In the device arm, MarginProbe was used to examine the main lumpectomy specimens and direct additional excision of positive margins. Intraoperative imaging was used in both arms; no intraoperative pathology assessment was permitted. False-negative rates were 24.8 and 66.1 % and false-positive rates were 53.6 and 16.6 % in the device and control arms, respectively. In similar proportions of patients in both arms, the main lumpectomy specimen contained at least one positive margin. In patients with positive margins on initial lumpectomy specimens, an average of two margins was involved, with no difference between the two arms. Surgeons correctly identified all positive margins on the main specimen and removed additional tissue from

those involved margins in 33 of 147 cases (22 %) in the control arm, versus 101 of 163 (62 %) cases in the device arm ( $p < 0.0001$ ). 19.8 % of patients in the device arm underwent second procedures for reexcision of lumpectomy margins compared with 25.8 % of patients in the control arm, representing a 6 % absolute (23 % relative) reduction associated with MarginProbe use. With regard to reexcision procedures that were required because of positive margins originating from the main lumpectomy specimens the control arm rate was 20.8 % compared with 10.0 % in the device arm ( $p = 0.002$ ). Study limitations included that this study did not test whether the device would allow for less surgery to be performed if the specimens were carefully examined intraoperatively by pathologists, with or without the selective use of frozen section. Although results are promising, additional large randomized trials and consensus support by way of published society/professional organization are necessary before this device can be considered standard of care.

Thill et al. (2014) assessed the benefit of MarginProbe in intraoperative margin assessment during breast conservation surgery (BCS) of ductal carcinoma in situ, the associated reduction of re-excisions and the cosmetic outcome in 42 patients. The study was a multi-center, single arm, post market study enrolling 55 patients and was conducted at three sites in Germany. During the study MarginProbe was used as an adjunctive tool to standard of care. Results were compared to a historical re-excision rate, defined as the number of re-excisions (26/67 patients, 39%) that had been performed on DCIS patients from the general screening. The device use was associated with a reduction in re-excision rates by 56%, from 39% to 17% ( $p = 0.018$ ). In 21% (9/42) of the cases use of the device led to a direct conversion to mastectomy due to extensive disease identified, sparing an additional re-excision BCS. Study limitations include small number of participants and uncontrolled study design.

Allweis et al. (2008) reported results of a randomized clinical trial in 300 patients (device:  $n = 149$ , control:  $n = 151$ ) assessing a real-time, intraoperative probe for positive margin detection in breast-conserving surgery. In the device group, the probe was applied to the lumpectomy specimen and additional tissue was excised according to device readings. Study arms were compared by reoperation rates and by correct surgical reaction confirmed by histology. In both arms surgeons were allowed to use any standard of care (SOC) intraoperative methods to evaluate margin status such as palpation, specimen imaging, and intraoperative gross and/or microscopic pathology assessment. Pathology data were collected for the primary lumpectomy and all repeat ipsilateral surgical procedures within 6 months. The device was only applied to the main lumpectomy specimen and was not used in reoperations. Reoperation rate between the two groups was not statically significant ( $p = 0.98$ ). The proportion of patients with long-term "excellent" or "good" cosmetic evaluation was similar in both arms (71% and 69% for the two groups, respectively ( $p = 0.71$ )). Data do not suggest improved reoperation rates compared to control.

**Optical Coherence Tomography of Breast or Axillary Lymph Node (CPT Codes 0351T, 0352T, 0353T, 0354T)**

Optical coherence tomography (OCT) is a high-resolution, near-infrared light imaging modality that has been proposed as a non-surgical method of assessing breast and axillary lymph node margins.

**Literature Review**

Randomized clinical trial data are lacking in the published, peer-reviewed scientific literature. Butler-Henderson et al. (2014) published a systemic review of 27 studies examining current intraoperative methods for assessing margin status. The final pathology status, statistical measures including accuracy of tumor margin assessment, average time impact on the procedure and second operation rate, were used as criteria for comparison between studies. One third (9/27) of the studies recruited subjects prospectively but did not act on results from intraoperative methods of assessment (IMA), (i.e. prospective observational). About 40% (11/27) of studies also recruited prospectively and acted on IMA results, (i.e. prospective experimental), whereas the remaining (7/27) studies were retrospective chart reviews. Overall, accuracy of IMA was well reported. Accuracy rates for ultrasound, frozen section and optical coherence tomography were 99.6%, 98.02% and 90%, respectively. Imprint cytology had a sensitivity of 80-85% and specificity of 85-100%. Optical coherence tomography reported a sensitivity of 100% and specificity of 82%, but average operation time was unavailable. Only one study examined the use of optical coherence tomography in breast cancer surgery. Additional operation time and second operation rate were not investigated. The authors note that caution is necessary before making any recommendation concerning its use in breast surgery.

Nguyen et al. (2009) reported results of a prospective, observational study. OCT demonstrated a sensitivity of 100% and specificity of 82% for OCT as a real-time method for margin assessment during breast-conserving surgery involving a total of 37 patients. OCT images were acquired from surgical margins of lumpectomy samples. Histologic findings identified nine true positives, nine true negatives, two false positives and no false negatives. The authors concluded that OCT shows potential as a real-time method for intraoperative margin assessment in breast-conserving surgeries. Study limitations include nonrandomized design and small sample size.

"Cigna Companies" refers to operating subsidiaries of Cigna Corporation. All products and services are provided exclusively by or through such operating subsidiaries, including Cigna Health and Life Insurance Company, Connecticut General Life Insurance Company, Cigna Behavioral Health, Inc., Cigna Health Management, Inc., QualCare, Inc., and HMO or service company subsidiaries of Cigna Health Corporation. The Cigna name, logo, and other Cigna marks are owned by Cigna Intellectual Property, Inc. © 2018 Cigna.

## PROVIDER POLICIES & PROCEDURES

### ELECTRIC TUMOR TREATMENT FIELD THERAPY (E.G. OPTUNE DEVICE)

The purpose of this document is to assist providers enrolled in the Connecticut Medical Assistance Program (CMAP) with the information needed to support a medical necessity determination for electric tumor treatment field therapy. By clarifying the information needed for prior authorization of services, HUSKY Health hopes to facilitate timely review of requests so that individuals obtain the medically necessary care they need as quickly as possible.

Tumor treatment field (TTF) therapy uses a noninvasive device to create alternating, wave-like electric fields to selectively disrupt mitosis in dividing cancer cells. TTF is approved for use in the treatment of glioblastoma multiforme (GBM), the most prevalent and primary malignant brain tumor in adults. The device is comprised of an electric field generator, a connection cable and box, transducer arrays, and batteries along with a charger, power supply and carrying bag. The transducer arrays are directly applied to the scalp and must be changed at least two times per week. The device is portable for use in normal daily activities and is typically worn for at least 18 hours per day.

#### CLINICAL GUIDELINE

Coverage guidelines for TTF therapy are made in accordance with the Department of Social Services (DSS) definition of Medical Necessity. The following criteria are guidelines only. Coverage determinations are based on an assessment of the individual and their clinical needs. If the guidelines conflict with the definition of Medical Necessity, the definition of Medical Necessity shall prevail. The guidelines are as follows:

Use of a device to generate TTF is generally considered medically necessary for adults (at least 22 years of age) with histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma) when used:

1. As monotherapy:
  - A. Following histologically or radiologically confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy; and
  - B. When intended as an alternative to standard medical therapy after surgical and radiation options have been exhausted; **OR**
2. As adjunctive therapy with temozolomide for newly-diagnosed histologically confirmed supratentorial glioblastoma following debulking surgery and completion of radiation therapy together with concomitant standard chemotherapy.

#### Initial Coverage

When all of the above criteria are met, an initial 3 months of TTF therapy will be approved.

#### Continuing Coverage:

In addition to meeting the above criteria, subsequent approval(s) for continuation of TTF therapy is based on:

1. Evidence of no documented disease progression by MRI or if MRI contraindicated, as evidenced by clinical re-evaluation; and

V1

1

Please note that authorization is based on medical necessity at the time the authorization is issued and is not a guarantee of payment. Payment is based on the individual having active coverage, benefits and policies in effect at the time of service.

To determine if a service or procedure requires prior authorization, CMAP Providers may refer to the *Benefit and Authorization Grids* summaries on [www.ct.gov/husky](http://www.ct.gov/husky) by clicking on "For Providers" followed by "Benefit Grids". For a definitive list of benefits and service limitations, CMAP Providers may access the CMAP provider fee schedules and regulations at [www.ctdssmap.com](http://www.ctdssmap.com).

2. Documentation that the individual has been wearing the device for at least 18 hours per day.

The use of a device to generate TTF is generally considered investigational and therefore not medically necessary for the treatment of other malignant tumors (e.g., breast, lung, melanoma, ovarian cancer, pancreatic cancer and solid tumor brain metastases) and for all other indications because the effectiveness has not been established.

The use of combined TTF therapy and chemo-immuno therapy other than temozolomide for the treatment of other malignant tumors is generally considered investigational and therefore not medically necessary because the effectiveness of this approach has not been established.

**NOTE: EPSDT Special Provision**

Early and Periodic Screening, Diagnosis, and Treatment (EPSDT) is a federal Medicaid requirement that requires the Connecticut Medical Assistance Program (CMAP) to cover services, products, or procedures for Medicaid enrollees under 21 years of age where the service or good is medically necessary health care to correct or ameliorate a defect, physical or mental illness, or a condition identified through a screening examination. The applicable definition of medical necessity is set forth in Conn. Gen. Stat. Section 17b-259b (2011) [ref. CMAP Provider Bulletin PB 2011-36].

**PROCEDURE**

Prior authorization for TTF therapy is required. Coverage determinations will be based upon a review of requested and/or submitted case-specific information.

**The following information is needed to review requests for TTF therapy:**

1. Fully completed Outpatient Prior Authorization Request Form or fully completed authorization request via on-line web portal;
2. A prescription from a licensed physician enrolled in the Connecticut Medical Assistance Program (CMAP);
3. Clinical information supporting the medical necessity of the treatment;
4. Pricing information\*;
5. Results of follow-up MRI or clinical re-evaluation (when requesting continuing coverage);
6. Documentation that the individual has been wearing the device for at least 18 hours per day (when requesting continuing coverage); and
7. Other information as requested.

\* Reimbursed at MSRP – 15%. Payment includes all necessary goods and services related to TTF therapy.

**EFFECTIVE DATE**

This Policy is effective for prior authorization requests for TTF therapy for individuals covered under the HUSKY Health Program beginning November 1, 2017.

**LIMITATIONS**

N/A

V1

2

Please note that authorization is based on medical necessity at the time the authorization is issued and is not a guarantee of payment. Payment is based on the individual having active coverage, benefits and policies in effect at the time of service.

To determine if a service or procedure requires prior authorization, CMAP Providers may refer to the *Benefit and Authorization Grids* summaries on [www.ct.gov/husky](http://www.ct.gov/husky) by clicking on "For Providers" followed by "Benefit Grids". For a definitive list of benefits and service limitations, CMAP Providers may access the CMAP provider fee schedules and regulations at [www.ctdssmap.com](http://www.ctdssmap.com).

**CODE:**

Code	Description
E1399	Durable medical equipment, miscellaneous

**DEFINITIONS**

1. **HUSKY A:** Connecticut children and their parents or a relative caregiver; and pregnant women may qualify for HUSKY A (also known as Medicaid). Income limits apply.
2. **HUSKY B:** Uninsured children under the age of 19 in higher income households may be eligible for HUSKY B (also known as the Children's Health Insurance Program) depending on their family income level. Family cost-sharing may apply.
3. **HUSKY C:** Connecticut residents who are age 65 or older or residents who are ages 18-64 and who are blind, or have another disability, may qualify for Medicaid coverage under HUSKY C (this includes Medicaid for Employees with Disabilities (MED-Connect), if working). Income and asset limits apply.
4. **HUSKY D:** Connecticut residents who are ages 19-64 without dependent children and who: (1) do not qualify for HUSKY A; (2) do not receive Medicare; and (3) are not pregnant, may qualify for HUSKY D (also known as Medicaid for the Lowest-Income populations).
5. **HUSKY Health Program:** The HUSKY A, HUSKY B, HUSKY C, HUSKY D and HUSKY Limited Benefit programs, collectively.
6. **HUSKY Limited Benefit Program or HUSKY, LBP:** Connecticut's implementation of limited health insurance coverage under Medicaid for individuals with tuberculosis or for family planning purposes and such coverage is substantially less than the full Medicaid coverage.
7. **Medically Necessary or Medical Necessity:** (as defined in Connecticut General Statutes § 17b-259b) Those health services required to prevent, identify, diagnose, treat, rehabilitate or ameliorate an individual's medical condition, including mental illness, or its effects, in order to attain or maintain the individual's achievable health and independent functioning provided such services are: (1) Consistent with generally-accepted standards of medical practice that are defined as standards that are based on (A) credible scientific evidence published in peer-reviewed medical literature that is generally recognized by the relevant medical community, (B) recommendations of a physician-specialty society, (C) the views of physicians practicing in relevant clinical areas, and (D) any other relevant factors; (2) clinically appropriate in terms of type, frequency, timing, site, extent and duration and considered effective for the individual's illness, injury or disease; (3) not primarily for the convenience of the individual, the individual's health care provider or other health care providers; (4) not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of the individual's illness, injury or disease; and (5) based on an assessment of the individual and his or her medical condition.
8. **Prior Authorization:** A process for approving covered services prior to the delivery of the service or initiation of the plan of care based on a determination by CHNCT as to whether the requested service is medically necessary.

# MEDICAL POLICY

**SUBJECT: TUMOR-TREATMENT FIELD THERAPY  
FOR GLIOBLASTOMA**

**EFFECTIVE DATE: 05/28/15  
REVISED DATE: 08/18/16**

**POLICY NUMBER: 6.01.45**

**CATEGORY: Technology Assessment**

**PAGE: 1 OF: 5**

- *If a product excludes coverage for a service, it is not covered, and medical policy criteria do not apply.*
- *If a commercial product, including an Essential Plan product, covers a specific service, medical policy criteria apply to the benefit.*
- *If a Medicare product covers a specific service, and there is no national or local Medicare coverage decision for the service, medical policy criteria apply to the benefit.*

## **POLICY STATEMENT:**

- I. Based upon our criteria and assessment of peer-reviewed literature, Tumor-Treatment Field (TTF) therapy using the NovoTTF-100A™ System for treatment of recurrent Glioblastoma multiforme (GBM) is considered **medically appropriate** when all of the following criteria have been met:
  - A. 1<sup>st</sup> or 2<sup>nd</sup> recurrence of GBM; and
  - B. The individual has a Karnofsky Performance Status (KPS) of 90 or greater; and
  - C. The individual has not received prior treatment with Bevacizumab; and
  - D. The device is to be used as monotherapy after failure of standard medical therapy (e.g., chemotherapy, surgery, and radiation therapy).
  - E. There is documented evidence the member is compliant with the TTF device during a one month trial period. Compliance is defined as use of the device for 18 hours or more per day during the one month trial period.
- II. Based upon our criteria and assessment of peer-reviewed literature, Tumor-Treatment Field (TTF) therapy using the NovoTTF-100A™ System for treatment of newly diagnosed Glioblastoma multiforme (GBM) is considered **medically appropriate** when the following criteria have been met:
  - A. The device is to be used as an adjunct with the chemotherapy drug temozolomide (TMZ); and
  - B. Following standard treatments that include maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

## **POLICY GUIDELINES:**

- I. The NovoTTF-100A™ System will be allowable for up to 6 months if the patient is compliant with the regimen. Continued use after 6 months will require additional documentation to show no progression in the patient's condition.
- II. The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM).
- III. The NovoTTF-100A™ System (Novocure Ltd., Haifa, Israel) was approved by the U.S. Food and Drug Administration (FDA) in April 2011 to deliver TTF therapy and is intended as a treatment for adult patients (22 years of age or older) with confirmed glioblastoma multiforme, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.
- IV. The NovoTTF-100A System (Novocure Ltd, Haifa, Israel) was approved by the U.S. Food and Drug Administration (FDA) in October 2015 to deliver TTF therapy and is intended as a treatment for adult patients (22 years of age or older) with newly-diagnosed glioblastoma multiforme when given along with the chemotherapy drug temozolomide following standard treatments that include surgery, and radiation therapy and chemotherapy used together.
- V. The Federal Employee Health Benefit Program (FEHBP/FEP) requires that procedures, devices or laboratory tests approved by the U.S. Food and Drug Administration (FDA) may not be considered investigational and thus these procedures, devices or laboratory tests may be assessed only on the basis of their medical necessity.

<b>SUBJECT: TUMOR–TREATMENT FIELD THERAPY FOR GLIOBLASTOMA</b>	<b>EFFECTIVE DATE: 05/28/15 REVISED DATE: 08/18/16</b>
<b>POLICY NUMBER: 6.01.45 CATEGORY: Technology Assessment</b>	<b>PAGE: 2 OF: 5</b>

### **DESCRIPTION:**

Glioblastoma multiforme (GBM) is the most common and aggressive primary intracranial tumor with approximately 33% surviving 1 year and less than 5% surviving more than 5 years. Median survival with optimal therapy has been reported to be 10-15 months with most tumors recurring within 7-9 months despite multimodal treatment (e.g. repeat surgery, re-irradiation and chemotherapy). Choice of chemotherapy for treatment in the case of recurrence varies but may include alkylating agents (e.g., lomustine, carmustine, procarbazine), re-treatment with temozolomide, and more recently, bevacizumab either alone or in combination with other agents. Overall survival after recurrence is relatively short even with optimal therapy. New or novel treatments such as TTF therapy are being investigated to improve survival in patients with GBM.

TTF therapy is delivered via the NovoTTF-100A™ System which is a battery-powered, portable device that generates alternating low intensity, intermediate electrical fields (100-300 kHz) by four disposable electrode arrays (replaced 1-2 times per week) that are noninvasively attached to the patient's shaved scalp placed in such a way to encompass the tumor. The alternating low intensity electrical field is thought to disrupt cell division of the cancer cells so that either cell division does not occur or it is ineffective, resulting in death of the cancer cells without harming the normal healthy cells. The device is used by the patient at home on a continuous basis (20-24 h/d) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.

### **RATIONALE:**

The Food and Drug Administration approval of the NovoTTF-100A system was based on a phase 3, multinational prospective RCT (Stupp et al, 2012). Two hundred thirty-seven patients with relapsed or progressive glioblastoma multiforme (GBM), despite conventional radiotherapy were randomized in a 1:1 ratio to receive TTF therapy (delivered by the NovoTTF-100A System) only (n=120) or the best standard of care chemotherapy (active control) (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the 28 participating clinical centers which were across 7 countries. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky Performance Status (KPS) score of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens, and 20% had failed bevacizumab prior to study enrollment. Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device. For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available. This RCT did not reach its primary end point of improved survival compared with active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared with 6.0 months in the active control group (hazard ratio, 0.86; 95% confidence interval [CI], 0.66 to 1.12; p=0.27). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared with 15.1% in the active control group (p=0.13). Objective radiologic responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) versus 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents used; severe (grades 3 and 4) toxicity was observed in 3% of participants. Longitudinal quality of life (QOL) data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group. In summary, this RCT failed to demonstrate the primary end point of improved survival with TTF therapy in comparison to

<b>SUBJECT: TUMOR–TREATMENT FIELD THERAPY FOR GLIOBLASTOMA</b>  <b>POLICY NUMBER: 6.01.45</b> <b>CATEGORY: Technology Assessment</b>	<b>EFFECTIVE DATE: 05/28/15</b> <b>REVISED DATE: 08/18/16</b>  <b>PAGE: 3 OF: 5</b>
---	--

chemotherapy. Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of 1 or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy.

A subgroup analysis of patient data of this phase 3 trial (Wong et al, 2014) evaluated the different characteristics of responders and nonresponders in the TTF group compared to the active control group. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p < 0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p < 0.001$ ) but not in chemotherapy arm ( $p = 0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

Analysis of the NovoTTF-100A™ Patient Registry Dataset (PRiDe) of 457 patients with recurrent GBM who were treated with NovoTTF therapy in the United States between October 2011 and November 2013 and comparison to patient data in the Phase 3 trial was performed (Mrugula et al 2014) to provide a larger dataset of patients with recurrent GBM treated with TTF therapy. No new adverse events in the PRiDe group of patients were reported compared to the Phase 3 trial group. However median overall survival was longer in the TTF group in the PriDe group (9.6 months) compared to the TTF group in the Phase 3 trial (6.6 months) or in the active chemotherapy group (6.0 months). Median treatment time was almost double for the TTF PriDe group compared to either the TTF or chemotherapy group in the Phase 3 trial. Favorable prognostic factors in the PriDe group included 75% or more daily compliance of the device, treatment with TTF at first recurrence, no prior treatment with bevacizumab, and Karnofsky Performance Score (KPS) 90 or greater. The authors suggest there are subsets of patients who derive significant benefit from TTF therapy and that TTF therapy using the NovoTTF-100A™ device is safe and efficacious to treat recurrent GBM.

The Food and Drug Administration approval of the NovoTTF-100A system for newly diagnosed glioblastoma multiforme (GBM) was based on the results from a clinical trial involving 695 patients newly diagnosed with GBM that compared those who used the device with temozolomide (TMZ) to those receiving TMZ alone (Stupp, 2015). Patients who used the device along with TMZ lived, on average, about 7 months with no disease progression compared to 4 months for those who had the drug alone. The device plus TMZ group survived for an average of 19.4 months after starting treatment compared to 16.6 months for those who were treated with TMZ alone.

The use of TTF therapy has been described in a number of case series. However, without evidence from additional high quality comparative studies, these studies provide limited additional evidence about whether TTF therapy improves outcomes compared with currently available therapy for GBM.

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines for Central Nervous System (v 1.2015) states that alternating electrical field therapy for glioblastoma may be considered as a treatment option for recurrent disease (Category 2B).

## CMS COVERAGE FOR MEDICARE PRODUCT MEMBERS

---

---

There is currently a Local Coverage Determination (LCD) for Tumor Treatment Field Therapy. Please refer to the following LCD website for Medicare Members: [https://www.cms.gov/medicare-coverage-database/details/lcd-details.aspx?LCDId=34823&ContrId=389&ver=9&ContrVer=1&CtrctrSelected=389\\*1&Ctrctr=389&s=41&DocType=Active&bc=AggAAIAAAAAAAAA%3d%3d&](https://www.cms.gov/medicare-coverage-database/details/lcd-details.aspx?LCDId=34823&ContrId=389&ver=9&ContrVer=1&CtrctrSelected=389*1&Ctrctr=389&s=41&DocType=Active&bc=AggAAIAAAAAAAAA%3d%3d&).

**Policy: MP306**

**Section: Medical Benefit Policy**

**Subject: Tumor Treatment Fields**

---

**I. Policy:** Tumor Treatment Fields

**II. Purpose/Objective:**

To provide a policy of coverage regarding Tumor Treatment Fields

**III. Responsibility:**

- A. Medical Directors
- B. Medical Management

**IV. Required Definitions**

1. Attachment – a supporting document that is developed and maintained by the policy writer or department requiring/authoring the policy.
2. Exhibit – a supporting document developed and maintained in a department other than the department requiring/authoring the policy.
3. Devised – the date the policy was implemented.
4. Revised – the date of every revision to the policy, including typographical and grammatical changes.
5. Reviewed – the date documenting the annual review if the policy has no revisions necessary.

**V. Additional Definitions**

Medical Necessity or Medically Necessary means Covered Services rendered by a Health Care Provider that the Plan determines are:

- a. appropriate for the symptoms and diagnosis or treatment of the Member's condition, illness, disease or injury;
- b. provided for the diagnosis, and the direct care and treatment of the Member's condition, illness disease or injury;
- c. in accordance with current standards of good medical treatment practiced by the general medical community.
- d. not primarily for the convenience of the Member, or the Member's Health Care Provider; and
- e. the most appropriate source or level of service that can safely be provided to the Member. When applied to hospitalization, this further means that the Member requires acute care as an inpatient due to the nature of the services rendered or the Member's condition, and the Member cannot receive safe or adequate care as an outpatient.

**Medicaid Business Segment**

Medical Necessity shall mean a service or benefit that is compensable under the Medical Assistance Program and if it meets any one of the following standards:

- (i) The service or benefit will, or is reasonably expected to, prevent the onset of an illness, condition or disability.
- (ii) The service or benefit will, or is reasonably expected to, reduce or ameliorate the physical, mental or development effects of an illness, condition, injury or disability.
- (iii) The service or benefit will assist the Member to achieve or maintain maximum functional capacity in performing daily activities, taking into account both the functional capacity of the Member and those functional capacities that are appropriate for members of the same age.

**DESCRIPTION:** Tumor Treating Fields, or TTF are low intensity, alternating electric fields within the intermediate frequency range. TTF disrupts cell division through physical interactions with key molecules during mitosis. TTF are generated via pairs of transducer arrays placed directly on the skin's surface in the region surrounding the tumor. The Optune™ delivery system is portable and is designed to allow individuals to continue their daily activities while receiving treatment. This non-invasive treatment is intended as a treatment for adults with histologically-confirmed glioblastoma multiforme (GBM).

**INDICATIONS: REQUIRES PRIOR AUTHORIZATION BY A PLAN MEDICAL DIRECTOR OR DESIGNEE**

**ALL Durable Medical Equipment provided for home use requires advanced determination of coverage. Devices furnished at inpatient or outpatient centers are NOT SEPARATELY REIMBURSABLE.**

The Optune™ tumor treatment field delivery system may be considered medically necessary when **all of the following** criteria are met:

1. As concomitant therapy with temzolomide in newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy; **and**
  - Member is an adult (defined by the FDA for this device as age 22 years or older); **and**
  - Karnofsky Performance Scale\* score of 70 or greater, or Eastern Cooperative Oncology Group (ECOG) performance status\*\* 0-1; **and**
  - Member is capable and agreeable to utilizing the device for a minimum of 18 hours per day

**or**

2. As a monotherapy for recurrent histologically-or radiologically-confirmed glioblastoma multiforme recurrence in the supratentorial region of the brain after receiving chemotherapy;
  - Member is an adult (defined by the FDA for this device as age 22 years or older); **and**
  - Karnofsky Performance Scale\* score of 70 or greater, or Eastern Cooperative Oncology Group (ECOG) performance status\*\* 0-1; **and**
  - Member is capable and agreeable to utilizing the device for a minimum of 18 hours per day

**NOTE:**

\* Karnofsky Performance Status Score:

100	Able to work. Normal; No complaints; No evidence of disease.
90	Able to work. Able to carry on normal activity; Minor symptoms.
80	Able to work. Normal activity with effort; Some symptoms.
70	Independent; not able to work. Cares for self; Unable to carry on normal activity.
60	Disabled; dependent. Requires occasional assistance; cares for most needs.
50	Moderately disabled; dependent. Requires considerable assistance and frequent care.
40	Severely disabled; dependent. Requires special care and assistance.
30	Severely disabled. Hospitalized, death not imminent.
20	Very sick. Active supportive treatment needed.
10	Moribund. Fatal processes are rapidly progressing

**\*\* Eastern Cooperative Oncology Group (ECOG) Performance Status**

0	Fully active, able to carry on all pre-disease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair
5	Dead

**LIMITATION:** Authorization for this device will be for a period of one (1) year.

**EXCLUSIONS:**

**For the Medicare business segment**, the use of TTF devices for the treatment of glioblastoma multiforme or any other indication is considered not reasonable and necessary, and therefore **NOT COVERED** per L34823 Tumor Treatment Field Therapy.

**For the Medicaid business segment**, the use of TTF devices for cancer treatment is considered experimental/investigational and **NOT COVERED** per MCOPS Memo #06/2016-006

The use of TTF devices to treat other malignant tumors (including but not limited to breast, lung, pancreatic, solid tumor brain metastases, ovarian and melanoma) and all other indications is considered Experimental, Investigational or Unproven and therefore, **NOT COVERED**.

**Note: A complete description of the process by which a given technology or service is evaluated and determined to be experimental, investigational or unproven is outlined in MP 15 - Experimental Investigational or Unproven Services or Treatment.**

**CODING ASSOCIATED WITH: Tumor Treatment Fields**

*The following codes are included below for informational purposes and may not be all inclusive. Inclusion of a procedure or device code(s) does not constitute or imply coverage nor does it imply or guarantee provider reimbursement. Coverage is determined by the member specific benefit plan document and any applicable laws regarding coverage of specific services. Please note that per Medicare coverage rules, only specific CPT/HCPCS Codes may be covered for the Medicare Business Segment. Please consult the CMS website at [www.cms.gov](http://www.cms.gov) or the local Medicare Administrative Carrier (MAC) for more information on Medicare coverage and coding requirements.*

77299 Unlisted procedure, therapeutic radiology clinical treatment planning [when specified as plan for using an electrical stimulation device for TTF]

A4555 Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

E0766 Electrical stimulation device used for cancer treatment, includes all accessories, any type

J8700 Temozolomide, oral, 5 mg

J9328 Injection, temozolomide, 1 mg

This policy will be revised as necessary and reviewed no less than annually.

**Devised:** 5/16

**Revised:** 7/16 (updated line of business specific coverage)

**Reviewed:** 5/17

**Effective Date: October 1, 2016**

**Subject: Tumor Treating Fields**

**Overview:** Tumor treating fields (TTF) therapy uses alternating electric fields to inhibit cell proliferation and leads to programmed cell death in the treatment of glioblastoma.

**Policy and Coverage Criteria:**

Harvard Pilgrim considers electric tumor treating fields (TTF) **medically necessary** for the treatment of histologically-confirmed glioblastoma (GBM) in members 18 years of age or older.

Harvard Pilgrim considers TTF **medically necessary** when used with temozolomide (TMZ) for the treatment of adult patients with newly diagnosed, supra-tentorial GBM following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

Harvard Pilgrim considers TTF **medically necessary** for the treatment of recurrent GBM when used as a monotherapy after surgical and radiation options have been exhausted.

**Exclusions:** Harvard Pilgrim considers TTF **investigational and/or not medically necessary** for the treatment of any condition not outlined above.

**Supporting Information:**

1. Technology Assessment

Tumor treating fields uses the Optune system which consists of 4 sets of insulated electrodes and an electric generator. The electrodes are attached to the shaved scalp of the patient who wears the device for at least 18 hours out of the day while low-intensity alternating electric fields are delivered to the tumor area. The alternating electric fields inhibit cell proliferation and lead to programmed cell death. The therapy targets dividing cells to stop tumor growth while sparing normal tissue.

2. Literature Review

Emerging evidence supports the use TTF to treat glioblastoma in adult patients.

Stupp et al (2015) conducted a phase 3 randomized trial to evaluate the efficacy and safety of TTF used in combination with TMZ maintenance treatment after chemoradiation therapy for patients with glioblastoma. The study enrolled 695 patients. The analysis included 210 patients randomized to TTF plus TMZ and 105 randomized to TMZ alone. Analysis was conducted at a median follow-up of 38 months. Median progression-free survival was 7.1 months in the TTF plus TMZ group and 4.0 months in the TMZ alone group. Median overall survival was 20.5 months in the TTF plus TMZ group and 15.6 months in the TMZ alone group. The trial was terminated based on the results of the interim analysis. The authors concluded that, based on the interim analysis of 315 patients with glioblastoma who had completed standard chemoradiation therapy, adding TTF to maintenance TMZ chemotherapy significantly prolonged progression-free and overall survival.

Mahadevan et al (2015) conducted a retrospective review of 40 patients with malignant gliomas who were treated with TTF or TTF with stereotactic radiosurgery (SRS). All patients had failed TMZ chemo-irradiation. Of the 40 patients, 12 received TTF and SRS. The median overall survival from initiation of TTF was 8 months. Those who were treated with TTF and SRS showed an increase in median overall survival compared with the TTF only group, 4 versus 12 months. The authors concluded there may be a benefit to combining TTF and SRS therapies to treat patients with recurrent glioblastoma.

Vymazal and Wong (2014) analyzed the results from two prior studies with demonstrated radiologic tumor response to single-agent TTF in patients with recurrent glioblastoma. The aim of the analysis was to better characterize tumor response patterns and evaluate associations between response, compliance, and overall survival. The overall response rate across both trials was 15%. Response duration was correlated with overall survival, and median overall survival for responders was 24.8 months. Compliance was linked with both improved response and survival. Seven of 16 responders exhibited tumor growth before shrinkage.

Stupp et al (2012) conducted a phase III trial of chemotherapy-free treatment of TTF (20-24 h/day) versus active chemotherapy in the treatment of patients with recurrent glioblastoma. A total of 120 patients received TTF alone and 117 patients received chemotherapy alone. Median survival was 6.6 months in the TTF group versus 6.0 months in the chemotherapy group, which held no significant difference. There was no difference in 1-year survival rate or progression-free survival rate at 6 months. There were significantly less severe adverse events in the TTF group (6%) versus the chemotherapy group (16%) and the quality of life analyses favored TTF therapy in most domains. The authors concluded that no improvement in overall survival was demonstrated, however efficacy and activity with TTF appears comparable to chemotherapy regimens that are commonly used for glioblastoma. Toxicity and quality of life clearly favored TTF.

**Pless and Weinberg (2011) published an expert opinion stating "[t]he proof of concept of TTFields has been well demonstrated in the preclinical setting, and the clinical data seem promising in various tumor types. The side effects of TTFields were minimal and in general consisted of skin reaction to the electrodes. There are a number of ways in which TTFields could be further evaluated, for example, in combination with chemotherapy, as a maintenance treatment, or as a salvage therapy if radiotherapy or surgery is not possible."**

Salzberg et al (2008) conducted an open, prospective pilot study to evaluate the safety, tolerability, and efficacy profile of TTF treatment in patients with locally advanced and/or metastatic solid tumors using the NovoTTF100A device. The cohort included 6 patients who were heavily pre-treated with several lines of therapy. Patients received TTF treatment for a minimum of 14 days. No serious adverse events occurred. Outcomes showed a partial response of a skin metastasis from primary breast cancer, 3 cases where tumor growth was arrested during treatment, and 1 case of disease progression. The authors concluded that while the cohort was small, the lack of therapy toxicity and the efficacy observed in data gathered indicates the potential of TTF as a treatment modality for solid tumors.

### 3. Professional/Governmental Organizations

FDA: Optune is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune with temozolomide (TMZ) is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

For the treatment of recurrent GBM, Optune is indicated following histologically- or radiologically-confirmed recurrence in the supra-tentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

[http://www.accessdata.fda.gov/cdrh\\_docs/pdf10/P100034S013b.pdf](http://www.accessdata.fda.gov/cdrh_docs/pdf10/P100034S013b.pdf)

NCCN: Approval of TTF by the FDA in 2011 for the treatment of recurrent glioblastoma was based on a clinical trial that randomized 237 patients to TTF or chemotherapy. Similar survival was seen in the two arms, and TTF therapy was associated with lower toxicity and improved quality of life. Due to lack of efficacy, not all panelists recommend the treatment.

191.0 – malignant neoplasm of brain – Cerebrum, except lobes and ventricles (i.e. basal ganglia, cerebral cortex, corpus striatum, globus pallidus, hypothalamus, thalamus)  
 191.1 – malignant neoplasm of the brain – frontal lobe  
 191.2 – malignant neoplasm of the brain – temporal lobe (i.e. hippocampus, uncus)  
 191.3 – malignant neoplasm of the brain – parietal lobe  
 191.4 – malignant neoplasm of the brain – occipital lobe  
 191.5 – malignant neoplasm of the brain – ventricles (i.e. choroid plexus, floor of ventricles)  
 191.6 – Cerebellum NOS (i.e. cerebellopontine angle)  
 191.7 – malignant neoplasm of the brain – brain stem (i.e. cerebral peduncle, medulla oblongata, midbrain, pons)  
 191.8 – malignant neoplasm of the brain – other parts of the brain (i.e. corpus callosum, tapetum)  
 191.9 – malignant neoplasm of the brain – brain, unspecified (i.e. cranial fossa NOS)

Medically necessary ICD-10 codes:

C71.0 – malignant neoplasm of cerebrum, except lobes and ventricles (i.e. malignant neoplasm of supratentorial NOS)  
 C71.1 – malignant neoplasm of frontal lobe  
 C71.2 – malignant neoplasm of temporal lobe  
 C71.3 – malignant neoplasm of parietal lobe  
 C71.4 – malignant neoplasm of occipital lobe  
 C71.5 – malignant neoplasm of cerebral ventricle  
 C71.6 – malignant neoplasm of cerebellum  
 C71.7 – malignant neoplasm of brain stem (i.e. malignant neoplasm of 4<sup>th</sup> cerebral ventricle, infratentorial malignant neoplasm NOS)  
 C71.8 – malignant neoplasm of overlapping sites of brain  
 C71.9 – malignant neoplasm of brain, unspecified

## Electric tumor treatment fields (ETTF) to treat glioblastoma (Optune)™

[Print](#)

These services may or may not be covered by your HealthPartners plan. Please see your plan documents for your specific coverage information. If there is a difference between this general information and your plan documents, your plan documents will be used to determine your coverage.

### Administrative Process

Prior authorization is not required for electric tumor treatment fields to treat glioblastoma.

### Coverage

[Back to top](#)

Electric tumor treatment fields (ETTF) therapy is generally covered subject to the indications listed below and per your plan documents.

### Indications that are covered

Electric tumor treatment fields (ETTF) therapy is covered as follows:

1. For patients with glioblastoma (GBM) that recurs or progresses after initial treatment; or

2. As a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM) in combination with temozolomide; or
3. For the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery, and completion of radiation therapy together with concomitant standard of care chemotherapy; or
4. For the treatment of recurrent GBM following histologically-or radiologically-confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

## Indications that are not covered

Electric tumor treatment fields (ETTF) is not covered for any additional indications.

## Definitions

[Back to top](#)

Tumor treating fields (TTFs) therapy uses alternating electric fields to inhibit cell proliferation and lead to programmed cell death. TTF therapy targets dividing cells to stop tumor growth while sparing normal tissue. The Optune™ TTF system is intended to treat patients with glioblastoma by using transducer arrays placed on the patient's scalp according to the tumor's location. Patients use the device on an outpatient basis for at least 18 hours per day for 4 weeks to several months. Intended benefits include stabilizing the disease, having fewer treatment-related adverse events, and improving quality of life.

## Codes

[Back to top](#)

*If available, codes for a procedure, device or diagnosis are listed below for informational purposes only, and do not guarantee member coverage or provider reimbursement. The list may not be all inclusive.*

Codes	Description
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

CPT Copyright American Medical Association. All rights reserved. CPT is a registered trademark of the American Medical Association.

## Products

This information is for most, but not all, HealthPartners plans. Please read your plan documents to see if your plan has limits or will not cover some items. If there is a difference between this general information and your plan documents, your plan documents will be used to determine your coverage. These coverage criteria may not apply to Medicare Products if Medicare requires different coverage. For more information regarding Medicare coverage criteria or for a copy of a Medicare coverage policy, contact Member Services at **952-883-7979** or **1-800-233-9645**.

<b>Medical Policy:</b>	E-5-005
<b>Topic:</b>	Tumor Treatment Fields (TTF)
<b>Section:</b>	Durable Medical Equipment
<b>Effective Date:</b>	March 20, 2017
<b>Issue Date:</b>	June 4, 2018
<b>Last Reviewed:</b>	May 2018

---

Electrical fields, known as "tumor treatment fields" (TTF), are created by low-intensity, alternating intermediate frequency (100-200 kilohertz [kHz]) electric currents delivered to the malignant tumor site by insulated electrodes placed on skin surface of the tumor site. As a result of the unique shape and electrical characteristics of dividing tumor cells, TTF exposure may damage the dividing cells through anti-microtubule mechanisms and could stop tumor growth while sparing normal tissue.

*This policy is designed to address medical guidelines that are appropriate for the majority of individuals with a particular disease, illness, or condition. Each person's unique clinical circumstances may warrant individual consideration, based on review of applicable medical records.*

**Policy Position** Coverage is subject to the specific terms of the member's benefit plan.

TTF may be considered medically necessary when **ALL** of the following indications are met:

- When it is used as an alternative to standard medical therapy, as a monotherapy; **and**
- For treatment of adult patients (22 years of age or older); **and**
- With histologically-confirmed glioblastoma multiforme; **and**
- Following histologically- or radiologically-confirmed recurrence in the Supratentorial region of the brain; **and**
- After receiving chemotherapy; **and**
- After surgical and radiation options have been exhausted.

**OR**

TTF may be considered medically necessary when **ALL** of the following indications are met:

- It is used as an adjunct to standard maintenance therapy; **and**
- For treatment for adult patients (22 years of age or older); **and**
- With histologically-confirmed glioblastoma multiforme; **and**
- When it is used with temozolomide; **and**
- With newly diagnosed, supratentorial glioblastoma, **and**
- Following maximal debulking surgery; **and**
- Completion of radiation therapy; **and**

- Together with concomitant standard of care chemotherapy.

TTF is considered experimental/investigational when above criteria are not met or for any other indications, and therefore, not covered because the safety and/or effectiveness of this service cannot be established by the available published peer-reviewed literature.

#### **Procedure Codes**

A4555, E0766

### **Place of Service: Inpatient/Outpatient**

Experimental/Investigational (E/I) services are not covered regardless of place of service.

The use of tumor treatment fields is typically an outpatient procedure which is only eligible for coverage as an inpatient procedure in special circumstances, including, but not limited to, the presence of a co-morbid condition that would require monitoring in a more controlled environment such as the inpatient setting.

### **The policy position applies to all commercial lines of business**

### **Denial Statements**

Services that do not meet the criteria of this policy will be considered experimental/investigational (E/I). A network provider can bill the member for the experimental/investigational service. The provider must give advance written notice informing the member that the service has been deemed E/I. The member must be provided with an estimate of the cost and the member must agree in writing to assume financial responsibility in advance of receiving the service. The signed agreement must be maintained in the provider's records.

**Subject:**

Tumor-Treatment Fields Therapy

**Description:****IMPORTANT NOTE:**

The purpose of this policy is to provide general information applicable to the administration of health benefits that Horizon Blue Cross Blue Shield of New Jersey and Horizon Healthcare of New Jersey, Inc. (collectively "Horizon BCBSNJ") insures or administers. If the member's contract benefits differ from the medical policy, the contract prevails. Although a service, supply or procedure may be medically necessary, it may be subject to limitations and/or exclusions under a member's benefit plan. If a service, supply or procedure is not covered and the member proceeds to obtain the service, supply or procedure, the member may be responsible for the cost. Decisions regarding treatment and treatment plans are the responsibility of the physician. This policy is not intended to direct the course of clinical care a physician provides to a member, and it does not replace a physician's independent professional clinical judgment or duty to exercise special knowledge and skill in the treatment of Horizon BCBSNJ members. Horizon BCBSNJ is not responsible for, does not provide, and does not hold itself out as a provider of medical care. The physician remains responsible for the quality and type of health care services provided to a Horizon BCBSNJ member.

Horizon BCBSNJ medical policies do not constitute medical advice, authorization, certification, approval, explanation of benefits, offer of coverage, contract or guarantee of payment.

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during of treatment. Tumor treatment fields (TTF) therapy is a new, noninvasive technology intended to treat glioblastoma using alternating electric fields.

Populations	Interventions	Comparators	Outcomes
Individuals: · With newly diagnosed glioblastoma multiforme on maintenance therapy after initial treatment	Interventions of interest are: · Tumor treating fields therapy as an adjunct to standard maintenance therapy	Comparators of interest are: · Standard maintenance therapy alone	Relevant outcomes include: · Overall survival · Disease-specific survival · Quality of life · Treatment-related morbidity
Individuals: · With progressive or recurrent glioblastoma multiforme	Interventions of interest are: · Tumor treating fields therapy as an adjunct or alternative to medical therapy	Comparators of interest are: · Standard medical therapy	Relevant outcomes include: · Overall survival · Disease-specific survival · Quality of life · Treatment-related morbidity

**Background****Glioblastoma Multiforme**

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults.<sup>1</sup> GBMs are grade IV astrocytomas, a rapidly progressing and deadly type of glial cell tumor that is often resistant to standard medical therapy (eg, bevacizumab, chemotherapy). Together, anaplastic astrocytomas and glioblastomas comprise approximately 38% of all brain and central nervous system tumors.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years, with a median age at diagnosis of 64 years. Glioblastomas have the lowest survival rate of any central nervous system tumor; in one report, about a third of patients survived to 1 year, and the 5-year survival rate was around 5%.<sup>2</sup>

**Clinical Context and Therapy Purpose**

The purpose of alternating electrical field therapy, more commonly known as tumor treating fields (TTF) therapy, is to provide a treatment option that is better than existing therapies for GBM. TTF has been investigated as an adjunct to temozolomide for the treatment of newly diagnosed GBM and as an alternative or adjunct to medical therapy for progressive or recurrent GBM.

**Treatment of Newly Diagnosed GBM**

The primary treatment for patients newly diagnosed with GBM is to resect the tumor to confirm a diagnosis while debulking the tumor to relieve symptoms of increased intracranial pressure or compression. If total resection is not feasible, subtotal resection and open biopsy are options. During surgery, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea) impregnated wafer. Due to the poor efficacy of local treatment, postsurgical treatment with adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of these 2 therapies is recommended. After adjuvant therapy, patients may undergo maintenance therapy with temozolomide. Maintenance temozolomide is given for 5 days of every 28-day cycle for 6 cycles.

Response and overall survival rates with temozolomide are higher in patients who have O<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT) gene promoter methylation (see 'Analysis of MGMT Promoter Methylation in Malignant Gliomas' - Policy #098 in the Pathology Section).

Prognostic factors for therapy success are age, histology, performance status or physical condition of the patient, and extent of resection. National Comprehensive Cancer Network recommendations include patient age and Karnofsky Performance Status score as important determinants of postsurgical treatment choice (see the Supplemental Information section).<sup>3</sup> For patients with good performance status, the most aggressive treatment (standard radiotherapy [RT] plus temozolomide) is recommended. For patients with poor performance status, only single treatment cycles or even palliative or supportive care are recommended. Hypofractionated RT is indicated for patients with poor performance status because it is better tolerated, and more patients are able to complete RT.

Treatment of GBM is rarely curative, and tumors will recur essentially all patients.

**Treatment of Recurrent GBM**

When disease recurs, additional debulking surgery may be used if the recurrence is localized. Due to radiation tolerances, re-radiation options for patients with recurrent GBM who have previously received initial external-beam radiotherapy are limited. There is no standard adjunctive treatment for recurrent GBM. Treatment options for recurrent disease include various forms of systemic medications such as the antivasculature endothelial growth factor drug bevacizumab, alkylating agents such as nitrosoureas (eg, lomustine, carmustine), or retreatment with temozolomide. Medical therapy is associated with side effects that include hematologic toxicity, headache, loss of appetite, nausea, vomiting, and fatigue. Response rates in recurrent disease are less than 10%, and the progression-free survival rate at 6 months is less than 20%.<sup>4</sup> There is a need for new treatments that can improve survival in patients with recurrent GBM or reduce the side effects of treatment while retaining survival benefits.

- Does TTF, when used as an adjunct to maintenance medical therapy in patients with newly diagnosed GBM, improve the net health outcome?
- Does TTF, when used as an adjunct to medical therapy in patients with recurrent GBM, improve the net health outcome?
- Does TTF, when used as an alternative to medical therapy in patients with recurrent GBM, improve the net health outcome?

The following PICOTS were used to select literature to inform this review.

### Patients

The relevant populations of interest are patients who have newly diagnosed GBM with good performance status or patients with recurrent GBM with good performance status. Newly diagnosed patients would have undergone initial treatment with surgery, RT, and chemotherapy and be receiving maintenance chemotherapy.

### Interventions

TTF therapy is a noninvasive technology intended to treat GBM on an outpatient basis and at home using electrical fields.<sup>4-6</sup> TTF therapy exposes rapidly dividing cancer cells to electric fields of low intensity and intermediate frequency (200 kHz) that alternate in perpendicular orientation. TTF therapy is proposed to inhibit tumor growth by 2 mechanisms: the arrest of cell proliferation by causing microtubule misalignment in the mitotic spindle of rapidly dividing tumor cells and apoptosis due to movement of macromolecules and organelles during telophase.<sup>5,6</sup> Preclinical studies have indicated that the electric fields may also make the cells more susceptible to chemotherapy.

Optune (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

### Comparators

The following practice is currently being used to make decisions about newly diagnosed GBM: maintenance chemotherapy with temozolomide alone.

The following practices are currently being used to make decisions about recurrent GBM: medical therapy.

TTF therapy might also be compared with palliative or supportive care, where survival rarely exceeds 3 to 5 months.<sup>4</sup>

### Outcomes

The general outcomes of interest are whether TTF improves survival or quality of life during treatment and, because most GBMs recur, the time to tumor recurrence. Measures of cognitive status and quality of life measures are also of interest to determine whether TTF alters the decline in cognition and quality of life that occur with GBM. Also, adverse events of treatment such as side effects of chemotherapy and the possibility of seizures need to be assessed.

### Timing

Due to the rapid progression of GBM, the time of interest for both progression-free survival and overall survival is months.

### Setting

The setting is outpatient care by an oncologist or neuro-oncologist.

### Regulatory Status

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (18 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>9</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

FDA product code: NZK.

### Related Policies

- Analysis of MGMT Promoter Methylation in Malignant Gliomas (Policy #098 in the Pathology Section)
- Radiation Therapy for Primary Craniospinal Tumors and Neurologic Conditions (Policy #100 in the Radiology Section)
- Intracavitary Balloon Catheter Brain Brachytherapy for Malignant Gliomas or Metastasis to the Brain (Policy #077 in the Radiology Section)

### Policy:

(NOTE: For Medicare Advantage, please refer to the Medicare Coverage Section below for coverage guidance.)

1. Tumor treating fields therapy to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in members with newly diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and/or chemotherapy under the following conditions:

- Adult patients ≥18 years of age
- Supratentorial tumor
- Karnofsky Performance Status score ≥70%
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (see Policy Guidelines).

2. Tumor treating fields therapy is considered **investigational** in all other conditions including but not limited to the following situations:

- As an adjunct to standard medical therapy (e.g., bevacizumab, chemotherapy) for members with progressive or recurrent glioblastoma multiforme
- As an alternative to standard medical therapy for members with progressive or recurrent glioblastoma multiforme
- For brain metastases
- For cancer in areas other than the brain.

**Medicare Coverage:**

There is no National Coverage Determination (NCD). In the absence of an NCD, coverage decisions are left to the discretion of Local Medicare Carriers. Nori Healthcare Services, LLC, the Local DME Medicare Carrier for jurisdiction JA, has issued determination L34823 Tumor treatment field therapy. Per LCD L348 Tumor treatment field therapy, (E0766) will be denied as not reasonable and necessary. Per Local Policy Article A52711, HCPCS code A4555 is not valid for billing to Medicare and will be denied an invalid code.

For additional information, refer to Local Coverage Determination (LCD): Tumor Treatment Field Therapy (TTFT) (L34823). **Policy Guidelines:** (Information to guide medical necessity determination based on the criteria contained within the policy statements above.)

Progression was defined in the EF-14 trial (Stupp et al [2015, 2017]) according to the MacDonald criteria (tumor growth >25% compared with the smallest tumor area measured in the patient during the trial or appearance of 1 or more new tumors in the brain that are diagnosed radiologically as glioblastoma multiforme) The Food and Drug Administration label includes the following notices:

- Patients should use Optune for at least 18 hours a day to get the best response to treatment
- Patients should finish at least 4 full weeks of therapy to get the best response to treatment. Stopping treatment before 4 weeks lowers the chances of a response to treatment.

**RATIONALE:** This policy was created in 2013 and has been updated regularly with searches of the MEDLINE database. The most recent literature update was performed through April 5, 2018.

Evidence reviews assess the clinical evidence to determine whether the use of a technology improves the net health outcome. Broadly defined, health outcomes are length of life, quality of life, and ability to function including benefits and harms. Every clinical condition has specific outcomes that are important to patients and to managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of a technology, 2 domains are examined: the relevance and the quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice.

For this review, 3 indications are evaluated: (1) tumor treating fields (TTF) as an adjunct to maintenance chemotherapy in newly diagnosed patients following initial treatment with surgery, radiotherapy and chemotherapy and (2) TTF as an adjunct or (3) alternative to medical therapy (eg, bevacizumab, chemotherapy, progressive or recurrent glioblastoma multiforme (GBM)).

**Study Selection**

The PICOTS was used to select relevant studies.

- To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs.
- To assess longer term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.
- Within each category of study design, studies with larger sample size studies and longer duration were sought.

**TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM****Randomized Controlled Trials**

Stupp et al (2017) published results of the EF-14 multicenter, open-label phase 3 RCT that evaluated maintenance therapy with TTF for newly diagnosed GBM. The trial included 695 patients from 83 sites who had supratentorial GBM and had completed standard treatment consisting of biopsy or surgical resection followed by radiotherapy and chemotherapy (see Table 1). A Karnofsky Performance Status (KPS) score of 70 or higher was an additional inclusion criterion to ensure independence in activities of daily living, and patients with rapidly progressing GBM following radiochemotherapy were excluded from the trial. Patients were randomized in a 2:1 fashion to TTF plus maintenance temozolomide or maintenance temozolomide alone.

All patients were seen monthly for follow-up. Quality of life (QOL) was assessed every 3 months, and magnetic resonance imaging (MRI) was performed every 6 months until tumor progression. Tumor progression on MRI was adjudicated by a central review committee blinded to treatment group. The primary outcome was progression-free survival (PFS), and the secondary outcome was overall survival (OS). The analysis was by intention-to-treat, including 26 patients from the control arm who crossed over to TTF following the planned interim analysis.

In 2014, an independent data and safety monitoring board concluded from the planned interim analysis that the trial met its predefined boundaries for success (improvement in PFS and OS) and recommended trial termination. The Food and Drug Administration approved the trial termination, and the trial was closed to recruitment with 695 of the planned 700 participants randomized. Control arm participants were allowed to cross over to the experimental treatment at this time. The interim analysis, which the Food and Drug Administration considered for the 2015 expanded approval of Optune, was published by Stupp et al (2015).<sup>11</sup> At the time of the interim analysis, data were available for 210 patients randomized to TTF plus temozolomide and 105 patients to temozolomide alone. Follow-up of the remainder of the 695 enrolled patients continued after enrollment was closed.

**Table 1. Key Randomized Controlled Trial Characteristics for Newly Diagnosed Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions	
					Active	Comparator
Stupp et al (2017) <sup>10</sup> ; EF-14	U.S., E.U., South Korea, Israel	83	2009-2016	<ul style="list-style-type: none"> <li>· 695 newly diagnosed with GBM and treated by radiochemotherapy</li> <li>· KPS score ≥70</li> </ul>	TTF >18 h/d plus maintenance temozolomide (n=466)	Maintenance temozolomide alone (5 d every 28 d for 6 cycles) (n=229)

Case 1:20-cv-00194-WCG Filed 04/28/20 Page 630 of 1212 Document 11-2 109

GBM: glioblastoma multiforme; h/d: hours per day; KPS: Karnofsky Performance Status; TTF: tumor treatment fields.

Results of the final analysis of the EF-14 trial were similar to the interim analysis and are shown in Table 2. Both PFS and OS improved with the addition of TTF therapy to standard maintenance chemotherapy (ie, temozolomide). PFS increased by 2.7 mo ( $p<0.001$ ) and OS increased by 4.9 mo ( $p<0.001$ ) in the TTF group. The time to a decrease in mental function was 2.5 months longer with TTF therapy ( $p<0.01$ ).

There was a similar percentage of dropouts at the final analysis with 49 (11%) patients in the TTF group and 27 (12%) patients in the temozolomide alone group. More treatment cycles with temozolomide were administered in the TTF group (median, 6 for TTF group vs 5 for controls), a finding that is consistent with the longer PFS. Rates of adverse events were similar between the groups, including rates of seizures. In secondary analysis of patients who had not progressed, there was no reduction in health-related quality of life with TTF compared with temozolomide alone aside from "itchy skin".<sup>12</sup> Interpretation of this result is limited by the low percentage of patients who completed the health-related quality of life assessments at follow-up (65.8% of the 655 patients alive at 3 months and 41.7% of the 473 patients alive at 12 months). A mixed-model analysis, which accounts for missing data, confirmed the results of the mean change from base analysis.

**Table 2. Key Randomized Controlled Trial Results for Newly Diagnosed Glioblastoma**

Study	Final N (%)	Median PFS (95% CI), mo	Median OS (95% CI), mo	Systemic Adverse Events, n (%)	Seizures, n (%)	Time to 6-Point Decline in MMSE Score (95% CI), mo
Stupp et al (2017) <sup>10</sup>						
TTF + temozolomide	417 (89)	6.7 (6.1 to 8.1)	20.9 (19.3 to 22.7)	218 (48)	26 (6)	16.7 (14.7 to 19.0)

HR (95% CI)		0.63 (0.52 to 0.76)	0.63 (0.53 to 0.76)			0.79 (0.66 to 0.95)
P value		<0.001	<0.001	0.58		0.01

CI: confidence interval; HR: hazard ratio; MMSE: Mini-Mental State Examination; OS: overall survival; PFS: progression-free survival; TTF: tumor treatment fields.

Tables 3 and 4 display notable gaps identified in this trial, the major limitation is the lack of patient blinding to treatment assignment. However, PFS was assessed by investigators who were blinded to treatment and placebo effects on OS were expected to be minimal. Investigators considered it practically unfeasible (due to the heat and current of the TTF therapy) and ethically unacceptable to submit the control patients to repeated shaving of the head and continuous wear of a sham device over many months.

## Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for Newly Diagnosed GBM

The final analysis of the EF-14 trial, which included 695 patients from 83 sites, found a statistically and clinically significant increase of 2.7 months in PFS and increase of 4.9 months in OS with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. There was no sham control, and patients were not blinded to treatment assignment, but PFS was assessed by blinded evaluators, and placebo effects on the objective measure of OS were likely to be minimal. There was no evidence of a negative impact of TTF therapy on health-related quality of life, except for itchy skin from the transducers.

## TTF Therapy as an Adjunct or Alternative to Medical Therapy for Progressive or Recurrent GBM

### Randomized Controlled Trials

The 2011 Food and Drug Administration approval of the NovoTTF-100A System (now called Optune) was based on a phase 3 multinational RCT (EF-11), results of which were published by Stupp et al (2012).<sup>4</sup> This trial compared TTF therapy alone with physician's choice medical therapy in 237 adults who had relapsed progressive glioblastoma (see Table 5). Patients had failed conventional treatment with radiotherapy, chemotherapy, and/or surgery, and more than 80% of participants had failed 2 or more prior chemotherapy regimens. In this trial, the term chemotherapy also applied to targeted agents such as bevacizumab. Patient characteristics and performance of additional post-recurrence debulking surgery were similar in the 2 groups.

**Table 5. Summary of Key Randomized Controlled Trial Characteristics for Progressive or Recurrent Glioblastoma**

Study; Trial	Countries	Sites	Dates	Participants	Interventions

					117 patients treated with physician's choice of medical

11				glioblastoma · KPS score $\geq 70\%$	cycle	therapy <sup>a</sup>
----	--	--	--	---	-------	----------------------

EU: European Union; KPS: Karnofsky Performance Status; TTF: tumor treating fields.

<sup>a</sup> Medical therapy included bevacizumab, irinotecan, nitrosoureas, platinum-based chemotherapy (ie, carboplatin); temozolomide; or a combination of procarbazine, chloroethyl ether, and vincristine.

Participants were followed monthly, including laboratory tests. MRI images were evaluated at 2, 4, and 6 months from initiation of treatment, with subsequent MRIs performed according to local practice until disease progression. QOL questionnaires were completed every 3 months. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with participants' caregivers were used to assess mortality rates. The primary end point was overall survival. Secondary end points included PFS, the percentage of patients with PFS at 6 months, time to progression, 1-year survival rate, QOL, and radiologic response rate. End points were evaluated using intention-to-treat analysis.

The trial did not reach its primary end point of improved survival compared with active medical therapy (see Table 6). With a median follow-up of 39 months, 9% of patients had died. There was not a statistically significant difference in survival rates at 1, 2, and 3 years between groups. Patients in the TTF group did not, however, suffer the typical systemic side effects of chemotherapy. The most common adverse event in the TTF group was grade 1 and 2 contact dermatitis of the scalp, which resolved with topical corticosteroids and did not require treatment breaks. Control participants experienced grade 2, 3, or 4 events by organ system related to the pharmacologic activity of chemotherapy agents used. Hematologic events of grade 2 or greater were observed in 17% of chemotherapy patients compared with 3% of TTF patients. Gastrointestinal disorders of grade 2 or greater were identified in 17% of chemotherapy patients compared with 4% of TTF patients. Severe (grades 3-4) hematologic and gastrointestinal toxicity was observed in 7% of chemotherapy controls compared with 1% of the TTF group.

Longitudinal QOL data, available in 63 (27%) participants, showed no meaningful differences between groups for the domains of global health and social functioning. However, cognitive and emotional functioning domains favored TTF therapy. Symptom scale analysis was by treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

The trial had a number of limitations (see Tables 7 and 8), that included lack of blinding and high loss to follow-up. Discontinuation of TTF therapy occurred in 22% of patients due to noncompliance or inability to handle the device, usually within the first few days. In the control group, 21 (18%) patients did not return to the treatment site, and details on disease progression and toxicity were not available. Longitudinal QOL could be analyzed only for 27% of patients who remained on study therapy for 3 months. The trial was designed as a superiority trial and did not provide adequate evidence of noninferiority.

#### Nonrandomized Comparative Studies

Kesari et al (2012) conducted a post hoc analysis of the EF-11 trial (see Stupp et al [2012] above) to evaluate the efficacy of TTF in patients who had the first recurrence.<sup>13</sup> Some patients in the temozolomide alone group crossed over to receive TTF plus chemotherapy after the first recurrence, resulting in 144 patients who received TTF fields plus chemotherapy and 60 patients who received chemotherapy alone for recurrent GBM (see Table 9). Patient characteristics and

second-line treatments were well-balanced between the groups, with bevacizumab the most common second-line therapy. The median OS in patients treated with systemic therapy alone was 9.2 months (see Table 10). In comparison, the group of patients who received TTF therapy in addition to systemic therapy had a median OS of 11.8 months ( $p=0.043$ ).

A registry study published Mrugala et al (2014) assessed OS data from patients who received NovoTTF therapy in a real-world, clinical practice setting (see Table 9).<sup>14</sup> Concurrent treatment was not captured in the registry, and it is possible that some patients received combination therapy. Median OS in the PRiDe clinical practice dataset (9.6 mo) was reported as superior to that attained in the EF-11 pivotal trial (6.6 mo,  $p<0.001$ ) (see Table 10). More patients in the PRiDe registry were treated for first recurrence (33% vs 9%), and more had received bevacizumab as prior therapy (55% vs 19%). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

Hazard ratio (95% CI)	0.66 (0.05 to 0.86)		
P value	<0.001		

CI: confidence interval; OS: overall survival; TTF: tumor treating fields.

Post hoc analyses of the EF-11 pivotal trial have been reported. Wong et al (2014) published a subgroup analysis to determine characteristics of responders & nonresponders in the active treatment and active treatment control.<sup>15</sup> They found that responders had a lower grade of histology and lower daily dexamethasone use than nonresponders. A second post hoc analysis by Kanner et al (2014) of the EF-11 pivotal trial data was performed to evaluate OS among patients who finished at least 1 complete course of TTF or chemotherapy.<sup>16</sup> The investigators reported that median OS was 7.7 months in the TTF group compared with 5.0 months in the chemotherapy group ( $p=0.009$ ). These post hoc analyses are considered to be hypothesis-generating.

#### Section Summary: TTF Therapy as an Adjunct or Alternative to Chemotherapy for Progressive or Recurrent GBM

The single RCT for TTF as an alternative to chemotherapy reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. The noninferiority of TTF compared with chemotherapy might be considered a sufficient health benefit, if TTF reduced treatment toxicity. However, because the trial was not designed as a noninferiority trial no inferences of noninferiority compared with chemotherapy can be made. Physician's choice therapy during the trial was heterogeneous, although analysis indicates that survival was not affected by choice of chemotherapy. More patients in the TTF group than in the control group did not complete the treatment course. The number of patients who contributed QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators might have been subject to bias due to the lack of blinding.

A nonrandomized post hoc evaluation of the EF-14 trial suggests that TTF may improve survival when combined with chemotherapy for recurrent GBM. This analysis should be considered hypothesis-generating, and further study in high-quality RCTs is needed.

#### Summary of Evidence

For individuals who have newly diagnosed GBM on maintenance therapy after initial treatment who receive TTF therapy as an adjunct to standard maintenance therapy, the evidence includes an RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, & treatment-related morbidity. The EF-14 trial found a significant increase of 2.7 months in progression-free survival and an increase of 4.9 months in overall survival with the addition of TTF therapy to standard maintenance therapy (ie, temozolomide) in patients with newly diagnosed GBM. Although patients were blinded to treatment assignment, progression-free survival was assessed by blinded evaluators, and the placebo effects on the objective measure of overall survival are expected to be minimal. This technology represents a clinically significant option in the treatment of patients with GBM, for whom options are limited. The evidence is sufficient to determine that the technology results in a meaningful improvement in the net health outcome.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy. Because no serious adverse effects have been identified with TTF therapy, this raises the possibility that treatment with TTF might reduce the toxicity associated with treatment for recurrent GBM. A reduction in chemotherapy-associated toxicity without loss of efficacy would be considered a net health benefit. However, this RCT is not sufficient to permit conclusions on the efficacy of the device. Because the trial was not designed as a noninferiority trial, no inferences of noninferiority compared with chemotherapy can be made. Also, quality of life assessment was measured in an insufficient number of patients to reach firm conclusions on differences in quality of life between TTF therapy and medical treatment. The highest quality study of TTF combined with medical treatment for recurrent GBM is a post hoc analysis of the EF-14 trial. A high-quality, prospective RCT is needed. The evidence is insufficient to determine the effects of the technology on health outcomes.

#### Supplemental Information

**Clinical Input From Physician Specialty Societies and Academic Medical Centers** 2112

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic

medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

#### Practice Guidelines and Position Statements

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2018) include recommendations for the treatment of glioblastoma (see Table 11).<sup>3</sup> For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate methylguanine-DNA methyltransferase promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric field therapy is a category 1 recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a category 2B recommendation.

**Table 11. Guidelines for Adjuvant Treatment of Glioblastoma, by Age and Performance Status**

Age, y	KPS Score,%	Treatment Options	Category
≤70	≥60	· Standard RT plus concurrent and adjuvant temozolomide plus TTF · Standard RT plus concurrent and adjuvant temozolomide	1
≤70	<60	· Hypofractionated RT with/without concurrent or adjuvant temozolomide · Temozolomide · Palliative/best supportive care	2A
>70	≥60	· Hypofractionated RT plus concurrent and adjuvant temozolomide · Standard RT plus concurrent and adjuvant temozolomide plus TTF · Temozolomide alone · Hypofractionated brain RT alone	1
>70	<60	· Hypofractionated brain RT alone · Temozolomide alone · Palliative/best supportive care	2A

KPS: Karnofsky Performance Status; RT: radiotherapy; TTF: tumor treating fields.

#### U.S. Preventive Services Task Force Recommendations

Not applicable.

#### Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in Table 12. Of particular note are the phase 3 trials evaluating TTF therapy in non-small-cell lung cancer and pancreatic cancer. TTF therapy is an active area of research for mechanisms underlying its effects on cancer cells.

**Table 12. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>Ongoing</b>			
NCT01971281 <sup>a</sup>	A Phase II Study of TTFields (150 kHz) Concomitant With Gemcitabine and TTFields Concomitant With Gemcitabine Plus Nab-paclitaxel for Front-line Therapy of Advanced Pancreatic Adenocarcinoma	40	Dec 2017 (ongoing)
NCT01894061 <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2018
NCT02663271 <sup>a</sup>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFields and Pulsed Bevacizumab Treatment in Patients With Bevacizumab-refractory Recurrent Glioblastoma	18	Mar 2019
NCT02831959 <sup>a</sup>	Pivotal, Open-label, Randomized Study of Radiosurgery With or Without Tumor Treating Fields (TTFields) (150kHz) for 1-10 Brain Metastases From Non-small Cell Lung Cancer (NSCLC) (METIS)	270	Jul 2019
NCT02973789 <sup>a</sup>	LUNAR: Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields) Concurrent With Standard of Care Therapies for Treatment of Stage 4 Non-small Cell Lung Cancer (NSCLC) Following Platinum Failure	534	Dec 2021
NCT02743078 <sup>a</sup>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Aug 2022
NCT03377491 <sup>a</sup>	EF-27 Pivotal, Randomized, Open-label Study of Tumor Treating Fields (TTFields, 150kHz) Concomitant With Gemcitabine and Nab-paclitaxel for Front-line Treatment of Locally-advanced Pancreatic Adenocarcinoma (PANOV-3)	556	Dec 2022

NCT: national clinical trial.

<sup>a</sup> Denotes industry-sponsored or cosponsored trial.]

Horizon BCBSNJ Medical Policy Development Process:

This Horizon BCBSNJ Medical Policy (the "Medical Policy") has been developed by Horizon BCBSNJ's Medical Policy Committee (the "Committee") consistent with generally accepted standards of medical practice, and reflects Horizon BCBSNJ's view of the subject health care services, supplies or procedures, and in what circumstances they are deemed to be medically necessary or experimental/ investigational in nature. This Medical Policy also considers whether and to what degree the subject health care services, supplies or procedures are clinically appropriate, in terms of type, frequency, extent, site and duration and if they are considered effective for the illnesses, injuries or diseases discussed. Where relevant, this Medical Policy considers whether the subject health care services, supplies or procedures are being requested primarily for the convenience of the covered person or the health care provider. It may also consider whether the services, supplies or procedures are more costly than an alternative service or sequence of services, supplies or procedures that are at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of the relevant illness, injury or disease. In reaching this conclusion, the Committee considers generally accepted standards of medical practice. The Committee reviews and considers the following: all credible scientific evidence published in peer-reviewed medical literature generally recognized by the relevant medical community, physician and health care provider specialty society recommendations, the views of physicians and health care providers practicing in relevant clinical areas (including, but not limited to, the prevailing opinion within the appropriate specialty) and any other relevant factor as determined by applicable State and Federal laws and regulations.

### Disclaimer

State and federal law, as well as contract language, including definitions and specific inclusions/exclusions, take precedence over clinical policy and must be considered first in determining eligibility for coverage. Coverage may also differ for our Medicare and/or Medicaid members based on any applicable Centers for Medicare & Medicaid Services (CMS) coverage statements including National Coverage Determinations (NCD), Local Medical Review Policies (LMRP) and/or Local Coverage Determinations. Refer to the [CMS website](#). The member's health plan benefits in effect on the date services are rendered must be used. Clinical policy is not intended to pre-empt the judgment of the reviewing medical director or dictate to health care providers how to practice medicine. Health care providers are expected to exercise their medical judgment in rendering appropriate care. Identification of selected brand names of devices, tests and procedures in a medical coverage policy is for reference only and is not an endorsement of any one device, test or procedure over another. Clinical technology is constantly evolving, and we reserve the right to review and update this policy periodically. No part of this publication may be reproduced, stored in a retrieval system or transmitted, in any shape or form or by any means, electronic, mechanical, photocopying or otherwise, without permission from Humana.

### Description

Electric tumor treatment fields (ETTFs) are created by low-intensity, alternating intermediate frequency (200 kilohertz [kHz]) electric currents which are delivered to a malignant tumor site via insulated electrodes placed around the region of the body containing the tumor.

ETTF treatment first received US Food and Drug Administration (FDA) approval for monotherapy of adults (22 years age or older) with histologically- or radiologically-confirmed recurrent supratentorial glioblastoma (also known as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) following chemotherapy *after* surgery and radiation treatments have been exhausted. The FDA expanded the approval to treat individuals with newly diagnosed GBM when given along with the chemotherapy drug temozolomide following standard treatments that include surgery, chemotherapy and radiation therapy.

Humana's documents are updated regularly online. When printed, the version of this document becomes uncontrolled. Do not rely on printed copies for the most up-to-date version. Refer to [Medical and Pharmacy Coverage Policies](#) to verify that this is the current version before utilizing.

For information regarding **temozolomide**, please refer to Temodor (temozolomide) Pharmacy Coverage Policy.

Reportedly, the application of ETTFs to the surface of the scalp disrupts the rapid division of cancer cells within the brain while sparing nonproliferating brain tissue and the normal rate of cell division. An example of a FDA approved ETTF device includes, but may not be limited to, Optune (formerly known as the Novo TTF-100A System).

The Optune system is a portable battery operated device. Treatment parameters are preset by the device manufacturer and no electrical output adjustments are available to individuals; however, they must learn to change and recharge depleted batteries. Individuals carry the device with them to receive continuous treatment, typically recommended for at least 18 hours per day for four weeks. Electrodes must be replaced every few days and the scalp reshaved in order to maintain optimal contact.<sup>9</sup>

ETTFs are being studied as an adjunctive therapy for additional indications which include, but may not be limited to, breast cancer, lung cancer and pancreatic adenocarcinoma. **(Refer to Coverage Limitations section)**

Treatment planning software (eg, NovoTAL) is available and designed to be utilized prior to ETTF treatment. The software purportedly allows the physician to individualize treatment by determining optimal placement of the transducer arrays based on the individual's most recent magnetic resonance imaging (MRI) scan, head size and tumor location.<sup>2</sup> **(Refer to Coverage Limitations section)**

## Coverage Determination

**All requests for electric tumor treatment fields require review by a medical director.**

Humana members may be eligible under the Plan for **ETTFs** for the following indications:

- Absence of any contraindication listed in the Coverage Limitations section; **AND**
- 22 years of age or older; **AND**
- Combined ETTF and temozolomide in individuals with histologically-confirmed newly diagnosed GBM limited to the supratentorial region following maximal

See the [DISCLAIMER](#). All Humana member health plan contracts are **NOT** the same. All legislation/regulations on this subject may not be included. This document is for informational purposes only.

Humana's documents are updated regularly online. When printed, the version of this document becomes uncontrolled. Do not rely on printed copies for the most up-to-date version. Refer to [Medical and Pharmacy Coverage Policies](#) to verify that this is the current version before utilizing.

debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy<sup>9</sup>; **OR**

- Monotherapy for individuals diagnosed with histologically- or radiologically - confirmed recurrent GBM limited to the supratentorial region following treatment with chemotherapy *after* surgical and radiation treatments have been exhausted<sup>9</sup>

*Coverage  
Limitations*

Humana members may **NOT** be eligible under the Plan for **ETTFs** for any indications other than those listed above including, but may not be limited to:

- If the following contraindications are present:
  - Active implanted medical device (eg, deep brain stimulators, spinal cord stimulators, pacemakers, defibrillators); **OR**
  - Bullet fragments; **OR**
  - Pregnancy; **OR**
  - Shunts; **OR**
  - Skull defects (eg, missing bone with no replacement)<sup>9</sup>; **OR**
- Treatment of other malignant tumors (eg, breast, lung, pancreas)

This is considered experimental/investigational as it is not identified as widely used and generally accepted for any other proposed use as reported in nationally recognized peer-reviewed medical literature published in the English language.

Humana members may **NOT** be eligible under the Plan for **treatment planning software** for use with ETTFs (eg, NovoTAL). This is considered experimental/investigational as it is not identified as widely used and generally accepted for the proposed use as reported in nationally recognized peer-reviewed medical literature published in the English language.

Humana's documents are updated regularly online. When printed, the version of this document becomes uncontrolled. Do not rely on printed copies for the most up-to-date version. Refer to [Medical and Pharmacy Coverage Policies](#) to verify that this is the current version before utilizing.

**Background** Additional information about **glioblastoma** may be found from the following websites:

- [American Cancer Society](#)
- [National Comprehensive Cancer Network](#)
- [National Library of Medicine](#)

**Medical Alternatives** Physician consultation is advised to make an informed decision based on an individual's health needs.

**Provider Claims Codes** Any CPT, HCPCS or ICD codes listed on this medical coverage policy are for informational purposes only. Do not rely on the accuracy and inclusion of specific codes. Inclusion of a code does not guarantee coverage and or reimbursement for a service or procedure.

CPT® Code(s)	Description	Comments
64999	Unlisted procedure, nervous system	Not Covered if used to report any procedure outlined in Coverage Limitations section
CPT® Category III Code(s)	Description	Comments
No code(s) identified		
HCPCS Code(s)	Description	Comments
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only	
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type	

Click [here](#) to view ICD-10-CM code(s) associated with this medical coverage policy.

See the [DISCLAIMER](#). All Humana member health plan contracts are **NOT** the same. All legislation/regulations on this subject may not be included. This document is for informational purposes only.

Humana's documents are updated regularly online. When printed, the version of this document becomes uncontrolled. Do not rely on printed copies for the most up-to-date version. Refer to [Medical and Pharmacy Coverage Policies](#) to verify that this is the current version before utilizing.

<b>Medical Terms</b>	<p><b>Adenocarcinoma</b> – A form of cancer that involves cells from the lining of the walls of many different organs of the body.</p> <p><b>Adjunct</b> – Something joined or added to another thing but not essentially a part of it.</p> <p><b>Astrocytoma</b> – A tumor that begins in the brain or spinal cord in small, star-shaped cells called astrocytes.</p> <p><b>Debulking</b> – Surgically removing all or most of the substance of a tumor or lesion without removing it entirely.</p> <p><b>Electrode</b> – Electrical lead or wire through which current may flow.</p> <p><b>Glioblastoma Multiforme</b> – A malignant rapidly growing central nervous system (CNS) tumor.</p> <p><b>Histologically-Confirmed</b> – The diagnosis of cancer has been confirmed by examining some of the cancerous tissue under a microscope.</p> <p><b>Malignant</b> – Characterized by uncontrolled growth; cancerous, invasive or metastatic.</p> <p><b>Monotherapy</b> – Therapy that uses one type of treatment, such as radiation therapy or surgery alone, to treat a certain disease or condition.</p> <p><b>Palliative</b> – Reducing the intensity of a disease; ease without curing.</p> <p><b>Proliferate</b> – To increase in number or spread rapidly and often excessively.</p> <p><b>Radiation Therapy</b> – Cancer treatment in which high levels of energy rays (X-rays) are used to destroy or shrink cancer cells.</p> <p><b>Supratentorial</b> – Relating to, occurring in, affecting or being the tissues overlying the tentorium cerebelli.</p> <p><b>Temozolomide</b> – A drug that is used for treating cancer, which interferes with the development of cancer cells, slowing their growth and spread in the body.</p>
----------------------	---

Humana's documents are updated regularly online. When printed, the version of this document becomes uncontrolled. Do not rely on printed copies for the most up-to-date version. Refer to [Medical and Pharmacy Coverage Policies](#) to verify that this is the current version before utilizing.

**Tentorium Cerebelli** – Arched fold of dura mater that separates the two major parts of the brain, the cerebrum above from the cerebellum below.

**Tumor** – Abnormal growth of tissue resulting from uncontrolled, progressive multiplication of cells and serving no physiological function; a neoplasm.

**WHO Classification of Central Nervous System (CNS) Tumors** – Uses molecular parameters in addition to histology to define many tumor entities, which formulates a concept of how CNS tumor diagnoses should be structured in the molecular era. Grading helps to understand the aggressiveness or malignancy of a tumor.

## Commercial Medical Policy

### Medical Policy Bulletin

Title: Tumor Treating Fields

Policy #: 07.03.26

The below medical or claim payment policy is applicable to the Company's commercial products only. Policies that are applicable to the Company's Medicare Advantage products are accessible via a separate [Medicare Advantage policy database](#).

The Company makes decisions on coverage based on Policy Bulletins, benefit plan documents, and the member's medical history and condition. Benefits may vary based on contract, and individual member benefits must be verified. The Company determines medical necessity only if the benefit exists and no contract exclusions are applicable.

When services can be administered in various settings, the Company reserves the right to reimburse only those services that are furnished in the most appropriate and cost-effective setting that is appropriate to the member's medical needs and condition. This decision is based on the member's current medical condition and any required monitoring or additional services that may coincide with the delivery of this service.

This Medical Policy Bulletin document describes the status of medical technology at the time the document was developed. Since that time, new technology may have emerged or new medical literature may have been published. This Medical Policy Bulletin will be reviewed regularly and be updated as scientific and medical literature becomes available. For more information on how Medical Policy Bulletins are developed, go to the About This Site section of this Medical Policy Web site.

#### Policy

Coverage is subject to the terms, conditions, and limitations of the member's contract.

MEDICALLY NECESSARY

## NEWLY DIAGNOSED GLIOBLASTOMA WHEN USED IN ADJUVANT TREATMENT

TTFIELDS are medically necessary and, therefore, covered for adult individuals (22 years of age or older) with newly diagnosed glioblastoma, when the individual meets all of the following criteria:

- Histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma)
- Tumor located in the supra-tentorial region of the brain
- Karnofsky Performance Score above 60
- Completed standard therapeutic options, such as maximum safe debulking surgery, concomitant temozolomide, or radiotherapy
- TTFIELDS is prescribed with adjuvant temozolomide (maintenance)
- Willingness to use the TTFIELDS device daily for at least 18 hours

## RECURRENT GLIOBLASTOMA WHEN USED AS A MONOTHERAPY

Alternating electric tumor treating fields (TTFIELDS) are medically necessary and, therefore, covered when used as a monotherapy for adult individuals (22 years of age or older) with recurrent glioblastoma, when the individual meets all of the following criteria:

- Histologically confirmed glioblastoma (World Health Organization grade IV astrocytoma)
- Tumor located in the supra-tentorial region of the brain
- Karnofsky Performance Score above 60
- Completed standard therapeutic options, such as maximum safe debulking surgery or systemic chemotherapy or irradiation
- Willingness to use the TTFIELDS device daily for at least 18 hours

## NOT MEDICALLY NECESSARY

TTFIELDS are considered not medically necessary and, therefore, not covered because the available published peer-reviewed literature does not support their use for the treatment of individuals with glioblastoma who have any of the following: an implanted pacemaker, programmable shunts, defibrillator, deep brain stimulator, other implanted devices in the brain, documented clinically significant arrhythmias, or evidence of increased intracranial pressure.

## EXPERIMENTAL/INVESTIGATIONAL

All other uses of TTFIELDS are considered experimental/investigational and, therefore, not covered because their safety and/or effectiveness cannot be established by review of the available published peer-reviewed literature.

## REQUIRED DOCUMENTATION

The Company may conduct reviews and audits of services to our members regardless of the participation status of the provider. Medical record documentation must be maintained on file to reflect the medical necessity of the care and services provided. These medical records may include but are not limited to: records from the professional provider's office, hospital, nursing home, home health agencies, therapies, and test reports.

## PRESCRIPTION (ORDER) REQUIREMENTS

Before submitting a claim to the Company, the supplier must have on file a timely, appropriate, and complete order for each item billed that is signed and dated by the professional provider who is treating the member. Requesting a provider to sign a retrospective order at the time of an audit or after an audit for submission as an original order, reorder, or updated order will not satisfy the requirement to maintain a

timely professional provider order on file.

#### PROOF OF DELIVERY

Medical record documentation must include a contemporaneously prepared delivery confirmation or member's receipt of supplies and equipment. The medical record documentation must include a copy of delivery confirmation if delivered by a commercial carrier and a signed copy of delivery confirmation by member/caregiver if delivered by the DME supplier/provider. All documentation is to be prepared contemporaneous with delivery and be available to the Company upon request.

#### CONSUMABLE SUPPLIES (WHEN APPLICABLE)

The durable medical equipment (DME) supplier must monitor the quantity of accessories and supplies an individual is actually using. Contacting the individual regarding replenishment of supplies should not be done earlier than approximately seven days prior to the delivery/shipping date. Dated documentation of this contact with the individual is required in the individual's medical record. Delivery of the supplies should not be done earlier than approximately five days before the individual would exhaust their on-hand supply.

If required documentation is not available on file to support a claim at the time of an audit or record request, the durable medical equipment (DME) supplier may be required to reimburse the Company for overpayments.

#### Guidelines

Tumor treating fields (TTFields) for the treatment of newly diagnosed and/or recurrent glioblastoma (GBM) utilizes a portable battery or power supply operated device which produces alternating electrical fields within the human body. TTFields are applied to individuals by electrically insulated surface transducer arrays. TTFields disrupt the rapid cell division exhibited by cancer cells.

TTFields are intended to harness electric fields to arrest the proliferation of tumor cells and to destroy them. The TTFields technology takes advantage of the special characteristics and geometrical shape of dividing cells, which make them susceptible to inhibiting cellular division during mitosis. The fields are said to alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used in the treatment of GMB has been specified to 200kHz.

#### KARNOFSKY PERFORMANCE STATUS (KPS)

A scale measuring the ability of individuals to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities.

KPS	Definition
100	Normal; no complaint; no evidence of disease
90	Able to carry on normal activity; minor signs of symptoms of disease
80	Normal activity with effort; some sign or symptoms of disease
70	Cares for self; unable to carry on normal activity or do active work
60	Requires occasional assistance, but is able to care for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospitalization is indicated, although death not imminent
20	Very sick; hospitalization necessary; active support treatment is necessary
10	Moribund; fatal processes progressing rapidly

## NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network® (NCCN®), a not-for-profit alliance of 27 leading cancer centers devoted to patient care, research, and education, is dedicated to improving the quality, effectiveness, and efficiency of cancer care so that patients can live better lives. NCCN® promotes the importance of continuous quality improvement and recognizes the significance of creating clinical practice guidelines appropriate for use by patients, clinicians, and other health care decision-makers. NCCN® provides a clinical practice guideline appropriate for use in the treatment of glioblastoma, both as a new diagnosis and in recurrent disease.

NCCN® provide clinical practice guidelines for central nervous system cancers on a variety of prognostic factors, such as: age, good performance status (KPS≥60), MGMT promotor status (methylated or unmethylated/indeterminate). When the medically necessary criteria listed in this medical policy are met, the NCCN® clinical practice guidelines endorse the use of TTFields, as follows:

### IN THE TREATMENT OF NEWLY DIAGNOSED GLIOBLASTOMA

Maximum resection + carmustine (BCNU) wafer with adjuvant treatments inclusive of standard brain RT (recommended dose is 60 Gy in 2.0 Gy fractions or 59.4 Gy in 1.8 Gy fractions) + concurrent temozolomide and adjuvant temozolomide + alternating electric field therapy.

### IN THE TREATMENT OF RECURRENT GLIOBLASTOMA

Resection with or without carmustine (BCNU) wafer AND palliative/best supportive care if poor performance, or systemic chemotherapy, or consider reirradiation (category 2B) or alternating electric field therapy for glioblastoma (category 2B).

## REGULATORY STATUS

On April 8, 2011, the FDA gave premarket approval for the NovoTTF-100A system (NovoCure Inc. Portsmouth, New Hampshire) for the treatment of adult patients (22 years of age or older) with histologically confirmed glioblastoma multiforme (GBM), following histologically or radiologically confirmed recurrence in the supra-tentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

On October 5, 2015, the FDA expanded approval for Optune™ (formerly NovoTTF-100A) system for the treatment of adult patients with newly diagnosed, supra-tentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

## BENEFIT APPLICATION

Subject to the terms and conditions of the applicable benefit contract, TTFields are covered as durable medical equipment (DME) under the medical benefits of most of the Company's products when the medical necessity criteria listed in this medical policy are met.

## Description

Glioblastoma multiforme (GBM) is the most prevalent and most fatal malignant brain tumor in adults, accounting for nearly 15% of all brain cancers. GBMs account for 46.6% of all malignant tumors with 12,150 new cases predicted annually. Malignant gliomas are histologically heterogeneous and invasive tumors that are derived from neuroglia, or glial cells, whose primary responsibility is to support the central

nervous system's neuron cells. GBMs are classified by the World Health Organization (WHO) as astrocytoma. The WHO provides a grading scale based on the most malignant regions of the tumors. Tumor grades depend upon degree of nuclear atypia, mitotic activity, microvascular proliferation, and necrosis, with increased anaplasia, corresponding to higher tumor grades. The 2007 WHO classification of GBM is a grade IV, indicating the most severe cancer grade, exhibiting rapid tumor growth leading to exceedingly poor prognosis. Eighty percent of individuals diagnosed with GBM will progress to recurrent disease, even after the initial surgical options have been exhausted. Survival expectancy for individuals with newly diagnosed GBM averages between 14.6 to 16.7 months with one-year survival rates of 35%. Following a GBM recurrence, the one-year survival rate is only approximately 20%, and median survival ranges from three to nine months.

Although the prognosis is dismal, the treatment options remain limited. The standard first-line treatment for a GBM is maximum surgical resection of the tumor. The National Comprehensive Cancer Network (NCCN®) has developed clinical practice guidance for the treatment of GBM. At present, the recommended treatment for an individual who is newly diagnosed with a histologically confirmed GBM is: maximum resection surgery, followed by radiotherapy (fractionated focal irradiation in daily fractions of 2 Gray [Gy] given 5 days per week for 6 weeks, for a total of 60 Gy). Gray is a unit of measurement for ionized radiation defined by the absorption of one joule of radiation per one kilogram of matter. In addition to radiotherapy, individuals are treated with concomitant continuous daily temozolomide (75 mg per square meter of body-surface area per day, 7 days per week from the first to the last day of radiotherapy), then subsequent cycles (6) of adjuvant temozolomide (150 to 200 mg per square meter for 5 days during each 28-day cycle). For disease recurrence, standard care includes surgical resection in combination with Gliadel® Wafer, stereotactic radiosurgery, and re-operation for additional tumor resection. Irrespective of the varying treatment protocols between the newly diagnosed and recurrent populations, GBM reoccurrence is still 80% and two-year survival rates remain a mere 27% following initial diagnosis. Acknowledging these dismal treatment outcomes, research has been conducted on new therapeutic agents for the treatment of glioblastoma. Stupp et al developed a new technology called tumor treating fields (TTFields) initially utilized and studied to treat the population with recurrent GBM disease.

TTFields is a technology utilizing electric activity through fields and currents to influence the of polarity of molecules, ions, and the cell membranes found in biological organisms to exert an effect on cellular process and impact cell division. By exposing cancer cells to alternating electric fields of low intensity and intermediate frequency, cellular polarity and ionic energy could be manipulated. This mechanism of action purported by TTFields (alternating electric fields) could selectively arrest cellular division (cytokinesis) in cancer cells by impairing normal mitosis and cytokinesis. TTFields are shown to have no effect on non-dividing cells, but to induce apoptosis in dividing cells. The electric fields interfere with cell division by causing misalignment of highly polarized subunits (microtubule monomers) in the mitotic spindle during the metaphase to anaphase transition and by dielectrophoretic movement of intracellular macromolecules and organelles during telophase. During cytokinesis, TTFields generate non-uniform intracellular fields, pulling organelles towards the neck that separates the newly forming daughter cells. In addition, TTFields interfere with the formation of the mitotic spindle by exerting forces on the charged tubulin subunits. Both processes lead to cell apoptosis and tumor growth inhibition. TTFields exert maximal effects when aligned to a cell's mitotic axis. As a cell's mitotic axis can occur randomly in any direction, additive cytotoxic effects are also observed when TTFields are applied in multiple sequential directions.

Individuals who utilize this technology for the treatment of GBM would need to place four transducer arrays onto their shaved scalp and connected to a portable, battery or power supply operated device (Optune, formerly the NovoTTF-100A system), which is preset to generate 200 kHz electric fields within the brain in two sequentially, perpendicular directions. The intensity of the field is also preset by the manufacturer at >0.7 V/cm. Treatment is intended to be continuous and take place in the home setting to allow the participants to maintain daily activities. Transducer arrays are supplied sterile, and prior to placement of the arrays, the scalp must be shaved carefully to limit the adverse effects (i.e., skin irritation, skin wounding).

Although uninterrupted treatment is recommended, individuals can take treatment breaks of up to an hour, twice per day, for personal needs (i.e., shower).

The electrodes themselves are made from high dielectric constant insulated ceramic discs soldered to a flexible circuit board. The flexible printed circuit incorporates the components required for delivering the current for each ceramic plate and for measuring the temperature. At the set parameters, the electrodes are not reported to cause significant heating due to dielectric losses of the insulation or induced fields in the target tissue.

The Optune system contains a separate software component for the use of clinical treatment planning. The NovoTAL™ system is a workstation based software tool that uses MRI head morphology, tumor size and location measurements, and tissue dielectric properties to optimize the TTFields' distribution and intensity within the tumor by determining the specific region of the brain to treat with the placement of paired arrays. The planning software is intended for use by physicians certified to prescribe electronic TTFields used for the treatment of GBM.

#### PEER REVIEWED LITERATURE

Kirson et al (2004) evaluated 11 types of cancerous cell lines in more than 500 in vitro culture dishes. The researchers calculated growth rates of the cells and measured cell proliferation. In all cell lines reviewed, each culture dish was exposed to TTFields for a period of 24-hour intervals at 100 kHz (at an intensity of 1.0–1.4 V/cm), which resulted in significant inhibition of cell proliferation. To test the relationship between TTFields' intensity and inhibition of cell proliferation, Kirson et al exposed mouse melanoma and rat glioma cell lines to TTFields of different intensities between 1 and 2.5 V/cm. Furthermore, authors reported that the inhibitory effect of TTFields on cell proliferation increased as intensity increased until complete proliferation arrest was achieved at intensities of 1.4 and 2.25 V/cm in melanoma and glioma cells, respectively. The authors reported on the most relevant findings regarding the prolongation of mitosis, stating in treated cells, mitosis seemed to begin normally but was prolonged for variable periods of time before completing cleavage into two daughter cells. In the 500 cells evaluated, the authors reported TTFields had exemplary effect on the cellular process. In the cells treated with TTFields, mitosis was not complete within the standard 3 hours. TTFields treated cells displayed proliferation arrest, and mitosis lasted on average  $124 \pm 91$  min (mean Standard Deviation [SD],  $n = 53$ ; 40–541 min), whereas in the controlled cells, the average mitosis duration was  $62 \pm 8$  min from cell rounding to cytokinesis with a mean SD of 12 and a range of 47–78 minutes. Their findings resulted in statistically significant prolongation of mitosis ( $P < 0.01$ , Mann-Whitney U test).

The authors reported in vivo studies with two animal tumor models. TTFields were generated between implanted (intra-dermal) wholly insulated wires placed on both sides of the tumor. The researchers placed two sets of paired identical insulated wires on the back of a mouse. The comparative in the mouse study was that only one of the pairs were connected to device, thus only exposing the area under the connected pair to TTFields treatment.

The researchers demonstrated that 100 KHz to 1 MHz alternating direction fields have significant specific effects on dividing cells. They reported that the areas treated with electric field of alternating direction provided evidence that all charges and polar molecules are subjected to forces of alternating direction so that ionic flows and dipole rotation oscillate. The basis of these effects during cytokinesis was shown to be that the unidirectional forces induced by disrupting mitotic spindle formation could result in physical disruption of the cell membrane and ultimately to apoptosis. During mitosis, exposure of cells to those fields results in one-fourth being destroyed as the formation of the cleavage furrow approached complete cell separation and violent membrane protrusions and cells exhibit disruption of microtubule spindle elements. Additionally, the authors reported that the direction of the placed electrical current dictates the magnitude of cellular disruption. Kirson et al concluded that when TTFields are placed parallel to the plane division, cells

exhibited more mitotic failure. Placement of the TTFields arrays is an important instruction when the technology is indicated in the treatment of cancers.

#### TUMOR TREATING FIELDS FOR THE TREATMENT OF RECURRENT, SUPRA-TENTORIAL GLIOBLASTOMA MULTIFORME

Kirson et al 2007 evaluated a single arm, pilot trial study on the safety and efficacy of TTFields treatment that was performed on 10 participants with recurrent GBM. Efficacy analysis was performed for recurrent GBM persons focusing on time to disease progression (TTP), progression-free survival at 6 months (PFS6), and overall survival (OS) as the primary outcomes for individuals treated with the NovoTTF-100A device. Based on such a small sample size no statistical hypothesis tests were measured. This study measured progression-free survival at 6 months (PFS6), producing a result of 50% (23–77%; 95% confidence interval). Ninety-five percent confidence intervals of survival proportions were calculated using Kaplan–Meier survival curves. The initial pilot study reported two of the ten participants surviving beyond the follow-up period, with the longest participant living for 124.0 weeks, differing from historical averages.

The authored indicated that the pilot study demonstrated TTP and OS values that were more than double the reported historical medians, and reported that TTFields treatment resulted in one complete response which was tumor free, confirmed by MRI ten months after stopping treatment, and one partial response which was still responding seven months after stopping treatment. Both were still progression free two years from treatment initiation. In addition, one participant had minimal response, and four had stable disease for over 4 months before progressing, with the authors suggesting that the device could conceivably halt tumor growth.

The seminal trial, which led to the Food and Drug Administration (FDA) granting approval of TTFields, was a prospective randomized, phase III trial (EF-11) conducted by Stupp et al. (2012). The EF-11 trial assessed TTFields as a monotherapy, without chemotherapy, compared to physician's standard chemotherapy. 237 participants were randomly assigned in a 1:1 ratio to receive either TTFields, (n=120) or an active control entailing the best available chemotherapy prescribed at the local investigator's discretion (n= 117). Participants were all at least 24 years old, with an average age of 54, had Karnofsky performance scores of  $\geq 70$  with limited other comorbidities. The study design reported that participants would receive baseline examinations and be tested monthly in laboratory. Magnetic resonance imaging (MRI) exams were repeated every second month, and quality of life questionnaires were completed every third month. The researchers allowed any number of prior treatments or recurrences of disease without limits. More than 85% of trial participants had failed two or more prior lines of chemotherapy (i.e.,  $\geq$  second recurrence), and nearly 20% had failed (or had a recurrence) while being treated with bevacizumab prior to enrollment. Tumor response and progression were determined by a blinded central radiology review. This study was designed to demonstrate device superiority over the pharmaceutical control.

The trial's primary outcome was overall survival (OS). Secondary endpoints were: progression-free survival (PFS), the percentage of individuals alive and progression-free at 6 months (PFS6), 1-year survival rate, radiological response rate (RR), quality of life, and safety. OS and PFS were computed from randomization until event or censored at last follow-up utilizing Kaplan–Meier survival method, with 2-sided log rank statistics for comparison. The study had an 80 percent power at a significance level of 0.05 to detect a 60 percent increase in median OS (Hazard Ratio [HR] 0.63). All analyses were performed using the intent to treat population of all randomized participants, individuals lost to follow-up were censored at the time of last contact. Treatment compliance limitations were disproportionately observed in the study as only 78% (93/120) completed one full cycle of the TTFields. Nearly a quarter of all participants in the TTFields treatment arm were noncompliant and discontinued, or failed to begin treatment. 113 of 117 participants (97%) in the active control group started chemotherapy, and all but one person completed one full treatment course. The study presented with follow-up limitations. Twenty-one participants randomized to the control group failed to return to the treatment site, limiting information on disease progression and

toxicity. Moreover, quality of life, a secondary outcome of the study, was only available for assessment on 63 or 27% of trial participants.

Compliance was recorded for those individuals in the TTFields arm who began treatment (n=116) by device downloads. The downloads recorded the treatment duration that TTFields therapy was delivered to each participant. The observed median compliance rate was 86 percent (41–98%) during each treatment month, resulting into a mean duration use of 20.6 hours per day. The study acknowledged variance among the level of disease progression (i.e., first recurrence versus multiple) by the participants but failed to produce comparisons amongst the control groups. Missing these comparisons limits the study's ability to determine the overall effectiveness of the TTFields as a monotherapy. Participants received either single agent or a combination of chemotherapeutic regimens. The percentage breakdown for the chemotherapy agents prescribed were as follows: individuals received bevacizumab (31%), or irinotecan (31%), followed by nitrosoureas (25%), carboplatin (13%), temozolomide (11%) or various other agents (5%). However, the study reported that among individuals treated with the active chemotherapy control, survival was not significantly affected by the choice of chemotherapeutic agent ( $p = 0.66$ ).

The statistical analysis of the survival data was tested for proportional hazards and the assumption of proportionality met using the Cox proportional hazards regression model. The Cox model was performed in two steps; first, all protocol pre-specified baseline variables were tested directly for interactions with OS; then a reduced model was performed testing the effect of all variables with significant interaction ( $p < 0.05$ ) with OS together on the treatment effect of TTFields versus active chemotherapy. At a median follow-up of 39 months, 220 trial participants had succumbed to their disease (93%). The primary endpoint failed to demonstrate a significant increase in mean overall survival between the two treatments. Median survival failed to report statistical significance but was marginally higher in the TTFields group compared to active control chemotherapy (6.6 versus 6.0 months, respectively). One-year survival proportion was 20% in both groups and was unable to demonstrate superiority over common chemotherapy treatments. The 2- and 3-year survival rates were reported as 8% (95% CI, 4-13) and 4% (95% CI, 1-8) versus 5% (95% CI, 3-10) and 1% (95% CI, 0-3) for TTFields versus active control, respectively. The reported hazard ratio was 0.86 (95% CI, 0.66-1.12) in favor of TTFields ( $p = 0.27$ ), indicating that TTFields may be at least equivalent and trending toward an improvement as compared to active chemotherapy. The trial failed to report statistically significant device superiority. Participants were not restricted based on prior treatments or recurrences. Many of the participants presented with advanced disease at trial initiation. As many as 40% of participants were included after the third disease occurrence, possibly decreasing the potential benefit from treatment. Trial results showed TTFields as a monotherapy provided similar, not superior, efficacy as best physician's choice chemotherapy in individuals afflicted with recurrent GBM, albeit superior quality of life and less toxicity resulting from treatment with chemotherapy.

Secondary trial outcomes were presented without adjustment. Quality of life measures were assessed using the QLQ-C30 questionnaire with brain-specific module (BN-20), and the measurements were presented as the change from baseline to 3 months for each of the subscale domains and symptoms scale. The researchers reported that both cognitive and emotional functioning were higher in the TTFields group compared to the chemotherapy group, with no difference in global health. The researchers reported that more objective radiological responses (partial and complete responses) were seen in the TTFields group than in the active control chemotherapy group (14 versus 7, respectively). Progression-free survival (PFS) resulted marginally in favor of participants in the TTFields treatment group, with median PFS reported as 2.2 and 2.1 months for TTFields versus the active control group, respectively (HR 0.81, 95% CI 0.60 - 1.09; log rank  $p = 0.16$ ). Authors state progression-free survival at 6 month was 21.4 percent (95% CI 13.5 - 29.3) in the TTFields group and 15.1 percent (95% CI 7.8 - 22.3) in the active control group (chi squared  $p = 0.13$ ). The authors were unable to claim statistical significance for the trial outcomes.

This study was limited by the inability to be blinded, which could introduce bias and compromise the quality of life assessments. Participant knowledge of their active participation limits the pinnacle prognostic factor

by creating bias. The disproportionate dropout rates are concerning. Many individuals stopped treatment prior to completing one month of treatment duration, and these individuals failed to be treated long enough to make substantial contributions to assist with determinations on device effectiveness. High rates of participant cross-over from chemotherapy into device treatment were observed in the study. Due to the nature of this disease and the dismal prognosis for individuals in this patient population, even marginal changes in overall survival and any increase in quality of life are clinically significant findings, as alternative to the current treatment modalities for individuals with recurrent GBM. Based on the slight improvement, trends observed in this trial suggest that treatment with TTFields may be considered an option.

Kanner et al performed a post hoc analysis to study the intent-to-treat (ITT) population in the TTFields treatment versus the best physician's choice chemotherapy. The authors report overall survival was significantly affected by duration that the TTFields device was worn. Not surprising, since this treatment is without a half-life and would require continuous application of the device to demonstrate a reduction in tumor growth. Stratifying population size to augment the desired results, the post hoc analysis measured outcomes within the population who fully completed at least one cycle (four weeks) of TTFields treatment. Based on those modifications, the researchers observed individuals who complied with treatment protocol of  $\geq 18$  hours daily ( $n=92$ ) had significantly longer overall survival medians, 7.7 versus 4.5 months than those who used treatment  $\leq 18$  hours ( $n=28$ ). Small sample sizes in the study diminish this power of the analysis, and the device may create adherence bias. However, a therapeutic response resulting in an observed mean overall survival increase of three months supports treatment effectiveness when compliance of the treatment protocol is adhered to.

A Patient Registry Dataset (PRiDe) followed 457 persons with recurrent GBM who received TTFields therapy was studied by Mrugala et al in a real-world, phase IV setting. Additional information on the safety and effectiveness of the therapy was assessed in the dataset. The primary outcome of the registry evaluated median overall survival, tolerability of the device, participant compliance and survival, and other prognostic factors. Mrugala reported overall survival (OS) and treatment using Kaplan-Meier methods and Cox proportional hazards model assessed participant characteristics and disease prognostic factors on survival. Evaluation was conducted with log-rank tests to compare OS and daily compliance, prior debulking surgery, Karnofsky Performance Score (KPS), number of recurrence, and prior bevacizumab use.

Overall survival between the PRiDe participants and those treated in the the seminal study with TTFields therapy, and physician's best chemotherapy, increased from 9.6 versus 6.6 versus 6.0 months, respectively. Overall survival rates at one- and two- years increased when compared to treatment arms (TTFields and chemotherapy) from the EF-11 study and PRiDe. As stated above, evidence supported daily compliance as a prognostic factor in TTFields therapy. Participants who achieved the recommended daily compliance of  $\geq 18$  hours a day had significantly longer ( $p=.0001$ ) overall survival --- 13.5 months versus 4.0 months when individuals reported less than  $\leq 18$  hours. Subgroup analysis of individuals treated at first recurrence ( $n=152$ ) demonstrated the longest median overall survival, resulting in 20 months. The overall survival reported in the first recurrence population is similar to more recent studies on the newly diagnosed, suggesting that TTFields may be an option as an effective therapy in GBM recurrence, if treatment is initiated at earliest recurrence.

The registry failed to evaluate participant use of combination therapy with TTFields and prescription programs, such as chemotherapy and anti-vascular endothelial growth factor agents. Outside of a clinical trial, the lack of recording information on other medical management regimens for participants resulted in critically missed analyses in demonstrating the effectiveness of TTFields as a therapy, potentially misrepresenting the true effectiveness of the device in the largest studied population. The registry highlights compliance as a key finding, supporting the adaptation of TTFields; however, it failed to record compliance data for more than one-third of all device users. Device safety and tolerability was proven outside of observational settings. Consistent with other trials, the adverse event most commonly observed

was associated with device-related skin irritation.

The registry presented with limitations, including lack of quality of life measures, as these were excluded in the real world follow-up, an important prognostic factor in overall health outcome from the original trial. Heterogeneity limitations exist within the registry as 67% of the total population were male (n=309), possibly significant considering the need to shave a user's scalp for successful placement of the treatment arrays when utilizing this device.

## TUMOR TREATING FIELDS FOR THE TREATMENT OF NEWLY DIAGNOSED GLIOBLASTOMA MULTIFORME

Stupp et al. 2015 conducted a multi-center, open-label, randomized phase III trial designed to evaluate the efficacy and safety of TTFIELDS following chemoradiation with temozolomide (TMZ) for treatment of newly diagnosed glioblastoma. The trial enrolled 695 participants with histologically confirmed supra-tentorial glioblastoma, who were progression-free following debulking surgery or biopsy, and who have completed standard concomitant chemoradiotherapy with TMZ. These individuals were randomized (2:1) to receive combination therapy of TTFIELDS plus temozolomide (TMZ) (n=466) or standard maintenance chemotherapy alone using TMZ (n=229). Randomization was stratified by participant characteristics: degree of resection, and O6-methylguanine-DNA methyltransferase (MGMT) methylation status. The primary outcome was progression-free survival (PFS) in the intent-to-treat (ITT) population and was assessed by independent reviewers (80% power; hazard ratio [HR], 0.78; allowing for 10% loss to follow-up; 2-sided  $\alpha$  level of 0.05). This study investigated shifted overall survival to a secondary outcome but with equal power (HR, 0.76; 2-sided  $\alpha$  = 0.05). To avoid an increase in the risk of a false positive result, overall survival was to only be tested statistically if the PFS was achieved.

In October, 2014, a safety monitoring committee reviewed the findings of an interim analysis reporting on the first 315 participants enrolled in the TTFIELDS plus temozolomide (n=210) and temozolomide (n=105) treatment groups. Pre-specified endpoints were achieved in the intent-to-treat population. After a median follow-up of 38 months (18-60 months), the median PFS in the TTFIELDS plus TMZ arm was 7.1 months from randomization (95% confidence interval [CI], 5.9 - 8.2 months) compared to 4.0 months (95% CI, 3.3 - 5.2) in the control group ([HR] 0.62; 98.7% CI, 0.43 - 0.89; stratified log-rank, P= 0.001). Overall survival in the per-protocol analysis also showed significant improvement. The combination therapy group (n=196) resulted in median OS of 20.5 months (95% CI, 16.7 - 25.0 months) compared to 15.6 months (95% CI, 13.3 - 19.1 months) in the TMZ alone group (n=84) ([HR], 0.64; 99.4% CI, 0.42 - 0.98; P =0.004). Based on the results of the interim analysis, the trial was terminated, and participants in the control group were allowed to receive TTFIELDS. The termination resulted in eleven individuals in the interim analysis and twenty-six participants overall to cross over and receive TTFIELDS treatment. The study demonstrated the addition of TTFIELDS to temozolomide treatment increased median progression-free survival in the ITT population by 3.1 months.

Per the study design, if tumor progression occurred, second-line chemotherapy was offered by local investigator's practice. Noteworthy, TTFIELDS would continue in the treatment arm, until the second radiological confirmed progression, or clinical deterioration, for a maximum of 24 months. Brain imaging was routinely performed, initially at baseline with contrast-enhanced magnetic resonance imaging (MRI) at two weeks prior to treatment initiation, then in two-month intervals until second radiologically confirmed progression in all study participants. Two-thirds of the TTFIELDS plus TMZ group (n=141) continued treatment with TTFIELDS beyond first tumor progression. The trial design to stop at second tumor progression may have clinical importance when considering the progression of disease and the use of TTFIELDS as a treatment option for individuals transitioning from a new diagnosis into recurrent GBM.

The authors reported median treatment duration of 5.8 months (1 - 58 months) with TTFIELDS. Three-quarters (n=157) of enrollees receiving TTFIELDS adhered to therapy. Protocol adherence was considered

wearing the device  $\geq 18$  hours per day on average during the first 3 treatment months. Further analyses in the ITT population showed the median overall survival was 19.6 months (95% CI, 16.6 - 24.4 months) in the TTFields plus temozolomide group compared to 16.6 months (95% CI, 13.6 - 19.2 months) in the temozolomide alone group ([HR], 0.74 95% CI, 0.56 - 0.98; stratified log-rank  $P=0.03$ ). The percentage of those affected by GBM alive at 2 years following enrollment was 43% in the TTFields plus temozolomide group and 29% in the TMZ alone group ( $P=0.006$ , a 14% increase of participants alive at two years in the treatment arm).

The original publication (interim analysis) of the EF-14 study was limited by the investigators stopping the trial earlier and allowing participant cross over. The interim analysis was completed after the initial 315 enrollees reached 18 month follow-up. The results in the initial per-protocol population only evaluated 196, 84 participants in the combination therapy (TTFields plus TMZ) or the TMZ alone arms, respectively. Additionally, as an open-label trial, no sham or placebo treatment was available for the control group. Investigators deemed the use of sham to be unethical, and impractical, and therefore the potential power of a placebo cannot be assessed. This may introduce adherence bias. The researchers acknowledge placebo bias would be unlikely to influence overall survival and progression-free survival. Following the original trial, which reported results that failed to provide evidence of statistically significant improvements in median overall survival, the primary study outcome shifted between the two seminal trials. In the original EF-11 trial, the primary endpoint was overall survival, and in this trial researchers adjusted the primary outcome to progression-free survival. The results of this study on newly diagnosed GBM, the addition of TTFields to maintenance temozolomide chemotherapy significantly prolonged progression-free and improved overall survival.

Stupp et al 2017 reported on the final analysis inclusive of the entire trial population ( $n=695$ ) from the open-label, randomized phase III trial designed to evaluate the effect of TTFields plus temozolomide (TMZ) versus maintenance TMZ alone on survival for individuals with glioblastoma. Stupp et al previously published the results from an interim analysis on the first 395 participants of the same study. The primary outcomes were consistent to the interim analysis.

The data set was locked on December 28, 2016, and the authors reported median treatment duration of 8.2 months (1 - 82 months) with TTFields. After a medium follow-up of 40 months (34 - 66 months), the median progression-free survival was 6.7 months (95% CI, 6.1 - 8.1 months) for individuals treated with combination therapy versus 4.0 months (95% CI, 3.8 - 4.4 months) for those treated with TMZ alone ([HR] 0.63, 95% CI, 0.52 - 0.76;  $P < 0.001$ ). The secondary outcome reported median overall survival duration of 20.9 months from randomization (95% CI, 19.3 - 22.7 months) in the TTFields plus TMZ group versus 16.0 months (95% CI, 14.0 - 18.4 months) for TMZ only ([HR], 0.63; 95% CI, 0.53 - 0.76;  $P < 0.001$ ). Both were found to be statistically and clinically significant. Analyzing the percentage of living participants over selected time periods from randomization resulted in 46% alive at 2 years, 26% alive at 3 years, and 13% alive at 5 years in the combination therapy arm, compared to the TMZ only arm reporting 31% alive at 2 years ( $p < 0.001$ ); 16% at 3 years ( $P=0.009$ ); and 5% at 5 years ( $P=0.004$ ). Significant percentage increases across each selected time period favoring adjuvant TTField therapy.

The median time to randomization was equal among the treatment arms with 3.8 month (range 1.7 - 6.2) and 3.7 months (range, 1.4 - 6.3) in the combination therapy, and the TMZ alone treatment groups, respectively. Kaplan-Meier estimates for survival were accessed at 6 months for the rate of progression-free survival between the two treatment groups. The authors reported on progression-free survival at 6 months as 56% (95% CI, 51% - 61%) for the TTFields group and 37% (30% - 44%) with TMZ only ( $P < 0.001$ ). Cox proportional hazards analyzed both overall survival and progression-free survival across factors: trial arms, age, sex, MGMT status, location, and county of residence. Results using Cox proportional hazards with 95% confidence intervals demonstrated several prognostic factors significantly improved OS; these prognostic factors include: TTFields treatment group (HR, 0.63, 0.53 - 0.76,  $P < 0.001$ ), female sex (HR, 0.76, 0.63 - 0.92,  $P = 0.005$ ), MGMT status (HR, 0.50, 0.41 - 0.62;  $P < 0.001$ ), younger age

(measured continuously, [HR], 0.978 per year, 0.969 - 0.985;  $P < 0.001$ ), and higher KPS (as a categorical variable in 10 point increments  $P < 0.001$ ).

Interestingly, fifty-five percent of participants had a gross tumor resection (95% of tumor removed) and 13% had only a biopsy performed, results indicating the extent of excision was not statistically significant when investigating overall survival ( $P = 0.183$ ). The addition of TTFields was not associated with an increase in systemic adverse events (AE) (48% versus 44%;  $P = 0.58$ ). Higher rates of AE found in the TTFields treated group were attributed to longer duration of TMZ treatment in the experimental group as a result of delayed disease progression. Investigators report inclusive criteria for TTFields treatment utilizing Karnofsky Performance Score (KPS). KPS is a scale measuring the ability of individuals to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities. The author reported time to sustain 10 point reduction in KPS significantly longer for the combination group versus the group treated with only TMZ (5.5 months; 95% CI, 5.0 - 6.3 months versus 3.9 months; 95% CI, 3.1 - 5.2 months, respectively; [HR], 0.80; 95% CI, 0.67 - 0.95;  $P = 0.009$ ).

Potentially important for future studies, a small majority of the experimental population (51%;  $n = 237$ ) continued TTFields treatment beyond first treatment progression. The investigators may want to evaluate, in the newly diagnosed population who elect to continue TTFields as a combination therapy beyond first progression, whether significant improvements are observed in progression-free survival and OS compared to the outcomes of the historical recurrent population. The recurrent population only has the option to utilize TTFields as a monotherapy. The largest study to date utilizing the TTFields technology presented with similar limitations as observed in the interim analysis (no sham, burden of use when utilizing the device). Another limitation in the final analysis was that quality of life data points were not recorded. Also, participant heterogeneity limitations exist since nearly 70% of the study participants were male and 89% were white.

The final analysis for the treatment of glioblastoma utilizing the TTFields technology demonstrated that the combination therapy of TTFields and temozolomide chemotherapy following standard concomitant TMZ and radiotherapy has shown to significantly improve progression-free survival and overall survival in the newly diagnosed population.

NovoCure Inc. of Portsmouth, New Hampshire (subsidiary of NovoCure Ltd., Haifa, Israel) was granted approval for the NovoTTF-100A system. The NovoTTF-100A Treatment Kit received US Food and Drug Administration (FDA) Premarket Approval on April 8, 2011 (P100034). The current supplement Optune™ System, which received FDA Premarket Approval on October 5, 2015 (P1000034/S013) was submitted to expand the indications for use: Optune™ System with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supra-tentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

In summary, TTFields has been demonstrated to be a safe and effective alternative treatment, and should be considered for individuals with either recurrent or newly diagnosed Glioblastoma. In 2015, The National Comprehensive Cancer Network® (NCCN®) clinical practice guidelines appropriateness in the treatment of central nervous system cancer for use of TTFields has shifted to consider category 3 in the recurrent population as a category 2B. A 2B category allows providers to consider the use of TTFields in treatment of recurrent disease. The NCCN® 2016 guidelines classifies alternating electronic fields therapy as a 2A grade for newly diagnosed glioblastoma individuals. NCCN® guidelines demonstrate TTFields used in concomitant treatment with adjuvant temozolomide following radiotherapy and concomitant temozolomide for the newly diagnosed. Indicating that use of TTFields could be used an initial treatment therapy, when prescribed with adjuvant temozolomide.

#### TUMOR TREATING FIELDS IN OTHER INDICATIONS

Researchers have initiated evaluations utilizing NovoCure's TTFields technology in the treatment of other

solid tumor indications. The various populations actively being investigated include cancers such as: non-small cell lung (NSCLC), brain metastases (1-5; 1-10) from NSCLC, pancreatic, ovarian, mesothelioma, and high grade glioma and ependymoma in children. Each of these separate indications has been either recently completed or is actively being studied in phase II trials to determine safety and efficacy with this new modality. The trials range in size, n= 5 in the child study to 82 participants in the mesothelioma trial. Variance exists between the primary outcomes researched in each of the new indications. In the ovarian and pancreatic cancers, the primarily investigated outcome was device related adverse effects and feasibility based on compliance as a result of the individual's early discontinuation of treatment. The tumor location could be a factor in compliance. Toxicity was the principal measurement in the non-small cell lung cancer study, whereas overall survival was the primary outcome in the mesothelioma trial. All studies listed time to progression, or progression-free survival as a secondary endpoint.

Non-small cell lung cancer is currently under investigation, with participants actively enrolled into a prospective, randomized controlled phase III trial aimed to test the efficacy and safety of TTFields in combination with PD-1 inhibitors or docetaxel as a second-line treatment. The researchers will assess the overall survival of participants with the TTFields and docetaxel or PD-1 inhibitors versus docetaxel or PD-1 alone in a superiority study design. Interestingly, if the primary outcome fails, the researchers will evaluate overall survival of those treated with TTFields and docetaxel versus PD-1 inhibitors alone in a separate, more challenging non-inferiority study. This study has a completion date of December 2020.

Evaluation of a trial on the feasibility of Optune for children with recurrent or progressive supra-tentorial high-grade glioma and ependymoma cancers was initiated in early 2017. This trial aims to demonstrate use of the Optune device as a feasible treatment option in the pediatric population and report treatment-related toxicities assessed by Common Terminology Criteria for Adverse Events v4.0. A total of 25 children are expected to participate in this trial. This study was the first trial, inclusive of the pivotal trials, that utilizes the TTFields technology that was not funded or sponsored by the device manufacture, NovoCure, Ltd. The pediatric study is sponsored by Pediatric Brain Tumor Consortium, with support from the National Cancer Institute (NCI).

## Coding

Inclusion of a code in this table does not imply reimbursement. Eligibility , benefits, limitations, exclusions, precertification/referral requirements, provider contracts, and Company policies apply .

The codes listed below are updated on a regular basis, in accordance with nationally accepted coding guidelines. Therefore, this policy applies to any and all future applicable coding changes, revisions, or updates.

In order to ensure optimal reimbursement, all health care services, devices, and pharmaceuticals should be reported using the billing codes and modifiers that most accurately represent the services rendered, unless otherwise directed by the Company .

The Coding T able lists any CPT , ICD-9, ICD-10, and HCPCS billing codes related only to the specific policy in which they appear .

➤ CPT Procedure Code Number(s)

N/A

Professional and outpatient claims with a date of service on or before September 30, 2015, must be billed using ICD-9 codes. Professional and outpatient claims with a date of service on or after October 1, 2015, must be billed using ICD-10 codes.

Facility/Institutional inpatient claims with a date of discharge on or before September 30, 2015, must be billed with ICD-9 codes. Facility/Institutional inpatient claims with a date of discharge on or after October 1, 2015, must be billed with ICD-10 codes.

➤ ICD - 10 Procedure Code Number(s)

N/A

Professional and outpatient claims with a date of service on or before September 30, 2015, must be billed using ICD-9 codes. Professional and outpatient claims with a date of service on or after October 1, 2015, must be billed using ICD-10 codes.

Facility/Institutional inpatient claims with a date of discharge on or before September 30, 2015, must be billed with ICD-9 codes. Facility/Institutional inpatient claims with a date of discharge on or after October 1, 2015, must be billed with ICD-10 codes.

➤ ICD -10 Diagnosis Code Number(s)

C71.0 Malignant neoplasm of cerebrum, except lobes and ventricles

C71.1 Malignant neoplasm of frontal lobe

C71.2 Malignant neoplasm of temporal lobe

C71.3 Malignant neoplasm of parietal lobe

C71.4 Malignant neoplasm of occipital lobe

C71.5 Malignant neoplasm of cerebral ventricle

C71.8 Malignant neoplasm of overlapping sites of brain

➤ HCPCS Level II Code Number(s)

A4555 Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

E0766 Electrical stimulation device used for cancer treatment, includes all accessories, any type

➤ Revenue Code Number(s)

N/A

## Clinical Review Criteria

### Tumor Treating Fields Therapy

**NOTICE:** Kaiser Foundation Health Plan of Washington and Kaiser Foundation Health Plan of Washington Options, Inc., provide these Clinical Review Criteria for internal use by their members and health care providers. The Clinical Review Criteria only apply to Kaiser Foundation Health Plan of Washington and Kaiser Foundation Health Plan of Washington Options, Inc. Use of the Clinical Review Criteria or any Kaiser Permanente entity name, logo, trade name, trademark, or service mark for marketing or publicity purposes, including on any website, or in any press release or promotional material, is strictly prohibited.

Kaiser Permanente Clinical Review Criteria are developed to assist in administering plan benefits. These criteria neither offer medical advice nor guarantee coverage. Kaiser Permanente reserves the exclusive right to modify, revoke, suspend or change any or all of these Review Criteria, at Kaiser Permanente's sole discretion, at any time, with or without notice. **Member contracts differ in their benefits. Always consult the patient's Medical Coverage Agreement or call Kaiser Permanente Customer Service to determine coverage for a specific medical service.**

## Criteria

### For Medicare Members

Source	Policy
CMS Coverage Manuals	None
National Coverage Determinations (NCD)	None
Local Coverage Determinations (LCD)	<a href="#">Tumor Treatment Fields Therapy (L34823)</a>
Medical Director Article	<a href="#">Tumor Treatment Field Therapy (TTFT) – Response to Comments</a>

### For Non-Medicare Members

- I. Tumor-treating fields (TTF) to treat primary (not recurrent) supratentorial glioblastoma multiforme (GBM) may be considered medically necessary when **ALL of the following** are met:
  - A. Patient is 18 years of age or older; and
  - B. Karnofsky Performance Status\* is 70% or higher; and
  - C. Documentation of histologically-confirmed primary glioblastoma multiforme; and
  - D. Patient has completed standard concomitant chemoradiation with temozolomide(TMZ); and
  - E. Disease did not progress through chemo radiation (possible "pseudo progression" does not exclude patients from receiving TTF) and
  - F. TTF will be administered concurrently with TMZ, unless TMZ has been ineffective, not tolerated, or is contraindicated and
  - G. TTF must be started no later than 60 days from the end of chemo radiation
- II. Continued treatment of TTF can be covered until the second radiological progression ( meaning 2 consecutive images showing tumor progression) or clinical deterioration

**All authorizations are for 90 days. Re-authorizations require updated clinical notes and imaging.**

\*Karnofsky Performance Status Scale

Condition	Value (%)	level of Functional Capacity
Able to carry on normal activity and to work; no special care needed	100%	No complaints; no evidence of disease
	90%	Able to carry on normal activity; minor signs or symptoms of disease
	80%	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; varying amount of assistance needed	70%	Cares for self; unable to carry on normal activity or to do active work
	60%	Requires occasional assistance but is able to care for most personal needs
	50%	Requires considerable assistance and

		frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; diseases may be progressing rapidly	40%	Disabled; requires special care and assistance
	30%	Severely disabled; hospital admission indicated although death not imminent
	20%	Very sick; hospital admission necessary; active supportive treatment necessary
	10%	Moribund; fatal processes progressing rapidly
	0%	Dead

The following information was used in the development of this document and is provided as background only. It is provided for historical purposes and does not necessarily reflect the most current published literature. When significant new articles are published that impact treatment option, KPWA will review as needed. This information is not to be used as coverage criteria. Please only refer to the criteria listed above for coverage determinations..

## Background

Glioblastoma (GBM), an incurable disease, has the highest incidence rate (3.19/100,000 population) amongst the central nervous system (CNS) tumors with an average survival of 15 months (Thakkar et al., 2014). Numerous genetic and environmental risk factors have been investigated but none is associated with a large population of GBM (Wrensch, Minn, Chew, Bondy, & Berger, 2002). The median age of diagnosis is 64 years and GBM is frequently found in the supratentorial region (Adams et al., 2013). GBM is an aggressive malignancy with poor prognosis and low survival. The first year relative survival rate is 35% and this estimate decreases over time (Ostrom et al., 2013) making the long term survival very harsh. Standard treatment consists of resection with combination of radiation and chemotherapy. These therapies, whether combined or utilized alone, do not significantly decrease mortality and do not lack adverse effects. Because GBM infiltrates the brain, it is prone to recurrence. Management of recurrence became challenging and therefore indispensable for better clinical outcomes. Different therapeutic options have been investigated but tumor treating fields (TTFields), a novel treatment, seems comparable to standard chemotherapy including Temozolomide and is less toxic (Roger Stupp et al., 2012).

TTFields, developed by NovoCure Ltd, is a medical device for the treatment of recurrent GBM. It is a portable, non-invasive, battery-operated and wearable device that disrupts the division of cancer cells and proliferation in the supratentorial region by delivering low-intensity and intermediate frequency (200 kHz) alternating electric fields via transducer arrays applied to the scalp by means of hypoallergenic ceramic disks, which are placed on the scalp using Hydrogel (Axelgaard Manufacturing Co, Ltd, Fallbrook, CA) as a conductor; It is believed that TTFields inhibits cytokinesis and microtubule assemble, and therefore inhibiting growth and causing death of cancer cells (Butowski, Wong, Mehta, & Wilson, 2013). The NovoTTF-100A received premarket approval from the Food and Drug Administration (FDA) on April 10, 2011 for treatment in adult patients with confirmed GBM, following confirmed recurrence in an upper region of the brain after receiving chemotherapy. The device is intended to be used independently and as an alternative to standard medical therapy after surgical and radiation options have been exhausted (FDA 2011).

The review of the safety and effectiveness of TTFields Therapy for the treatment of recurrent GBM in adults has been reviewed previously. However, it is being reviewed based on a request from the Clinical Review Unit with a focus on the combination of TTFields plus Temozolomide as maintenance therapy on newly diagnosed GBM. It is also being reviewed for coverage decision support.

## Medical Technology Assessment Committee (MTAC)

### Tumor Treatment Fields Therapy

#### 08/19/2013: MTAC REVIEW

**Evidence Conclusion:** The randomized phase III trial sought to compare the overall survival of subjects treated with the NovoTTF-100A alone to subjects treated with the best standard of care (BSC) chemotherapy available for recurrent GBM (Stupp, Wong et al. 2012). In the clinical study, 237 subjects with previously diagnosed GBM who experienced recurrence of their tumor or their condition worsened despite conventional therapy (surgery and chemo-radiotherapy followed by chemotherapy) were randomly assigned to receive either NovoTTF-100A stand-alone treatment or the BSC chemotherapy (as determined by the local physician). The primary endpoint for the

study was overall survival, as assessed by the log-rank test in the intent-to-treat population. In addition, the study examined the safety and tolerability of NovoTTF-100A treatment based on the incidence and severity of adverse events and toxicities. Secondary endpoints measured in the study included the progression free survival rate at 6 months, time to progression, one year survival rate, quality of life and radiological response rate. The ITT population includes all subjects who were randomized to the trial. At a median follow up of 39 months 93% of patients had died. The analysis was performed by the treatment group to which the subject was randomized. The study results showed that overall survival with the NovoTTF-100A System was no superior to that seen with active best standard of care chemotherapy. There was a slightly higher incidence of neurological adverse events in the NovoTTF-100A treated group (43.1%) compared to the best standard of care control group (36.3%). Mild to moderate skin irritation beneath the device electrodes was seen in 16% of NovoTTF-100A-treated subjects. NovoTTF-100A treated subjects experienced a lower frequency of the classic adverse events as seen with chemotherapy (such as gastrointestinal, hematological and infectious adverse events) with the best standard of care. Quality of life surveys indicated an improved quality of life in the NovoTTF-100A recurrent GBM subjects compared to the best standard of care recurrent GBM subjects. The trial was generally well designed and conducted with recruitment from 28 different clinics, randomization and minimal loss to follow up. Limitations identified by the authors include the somewhat heterogenous patient population with patients included after progression of one or several lines of prior chemotherapy. The authors also observed that the study could have benefited from a placebo or treatment-free control arm. Some limitations that are not highlighted by the authors include the decreasing number of subjects remaining after 12 months which may limit the ability to reliably estimate the long term survival outcomes. Furthermore, it is important to note that the primary investigator, as well as a number of other authors had financial and professional ties with the manufacturer of the device Novocure Ltd., Rye Beach, New Hampshire. Although the study failed to show that the NovoTTF-100A treatment is superior to chemotherapy with respect to overall survival the NovoTTF-100A treatment exhibits minimal toxicity, has clinically comparable primary and secondary effectiveness and better quality of life compared to the chemotherapies used in the control arm of the study.

**Articles:** A literature search was conducted revealing a small pilot trial and one larger pivotal study. The pilot study was an open-label prospective single arm study to assess the safety and effectiveness of TTFields for the treatment of GBM. The pivotal study was prospective, open label, best standard of care randomized control trial to compare the overall survival of subjects treated with NovoTTF-100A alone to subjects treated with the best standard of care chemotherapy available for recurrent GBM. In addition, the search revealed a case study illustrating one patient's success with TTFields therapy and one expert opinion article discussing the concept, evidence and future of TTFields. The clinical study that formed the FDA's basis for determining that the NovoTTF-100A System is safe and effective for its intended use was selected for review: Stupp R, Wong ET, Kanner AA, Steinberg D, Engelhard H, et al. NovoTTF-100A versus physician's choice chemotherapy in recurrent glioblastoma: A randomized phase III trial of a novel treatment modality. *European Journal of Cancer*. 2012;48, 2192-2202. See [Evidence Table](#).

The use of TT Fields Therapy does not meet the *Kaiser Permanente Medical Technology Assessment Criteria*.

### ***Tumor Treating Fields plus Temozolomide as maintenance therapy for Glioblastoma Multiforme (GBM)***

#### **03/21/2016: MTAC REVIEW**

**Evidence Conclusion:** The previous review on TTFields, completed in 2013, aimed to determine the safety and efficacy of TTFields therapy compared to standard medical therapy, for the treatment of recurrent GBM for adult patients. The study evaluating NovoTTF-100A versus Physician Choice Chemotherapy in recurrent glioblastoma (Roger Stupp et al., 2012) was reviewed and no improvement in overall survival was identified. The author of the review concluded that there was insufficient evidence to determine the safety and effectiveness of TTFields Therapy. Stupp, R., S. Taillibert, et al. (2015). "Maintenance Therapy With Tumor-treating Fields plus Temozolomide vs Temozolomide Alone for Glioblastoma: A Randomized Clinical Trial." See [Evidence Table 1](#). This randomized phase 3 trial, open label, parallel design, multicenter, (R. Stupp et al., 2015) intended to assess the efficacy and safety of TTFields in combination with temozolomide for treatment of patients with GBM after initial treatment with chemoradiation. After patients were diagnosed, they were initially treated with chemoradiation comprised of Temozolomide and concomitant radiation. Brain MRI was required 2 weeks prior to starting the maintenance treatment (to exclude progression cases). After completion of the initial treatment, patients were randomized at a ratio of 2 to 1 to receive TTFields + Temozolomide (n=466) or Temozolomide alone (n=229). TTFields was initiated within 4-7 weeks from the last dose of concomitant chemoradiotherapy. While Temozolomide was given on a basis of 150-200 mg/m<sup>2</sup>/d for 5 days every 28 days for 6-12 cycles, TTFields was delivered continuously (>18 hours/day) via 4 transducer arrays placed on the shaved scalp and connected to a portable medical device. The primary outcome was progression-free survival (PFS) in the intent-to-treat population (significance level of 0.01) and the secondary outcome was the overall survival (OS) in the per-protocol population (significance level of 0.006). Safety and tolerability were also evaluated. A total of 695 patients were recruited but

the trial was terminated after the interim analysis showed a benefit in Progression Free Survival. This interim analysis was conducted after the first 315 randomized patients reached a minimum of 18-month follow-up. Thus, data from 315 patients with 210 patients in the intervention group and 105 patients in the control group were analyzed. Baseline characteristics were nearly similar across the groups with median age of 57 years. The findings were based on the interim analysis. Patients who were treated with TTFields plus Temozolomide had longer PFS [7.1 months (CI, 5.9 – 8.2)] than those who were treated with Temozolomide alone [4 months (95%CI, 3.3 – 5.2)]. Likewise, patients who were treated with TTFields plus Temozolomide had longer OS [20.5 months (16.7 - 25)] than those who were treated with Temozolomide alone [15.6 months (CI, 13.3 – 19.1)]. In addition, no major increases in toxic effects were associated with the intervention. The most common adverse events were thrombocytopenia, mild to moderate skin irritation, and general disorders. In conclusion, the combination of TTFields plus Temozolomide prolonged PFS as well as OS compared to Temozolomide alone for the maintenance treatment of patients with GBM. However, this is an interim analysis with less than 50% of participation with exclusion of patients with early progression decreasing the quality of the evidence. MTAC will re-review the technology once full data are analyzed. Conclusion: The interim analysis with less than 50% participation suggests that TTF plus Temozolomide may prolong progression-free survival and overall survival versus Temozolomide alone. Nevertheless, the study failed to include patients with severe prognosis, therefore results should be interpreted with cautious. Other pitfalls remain in the open-label nature of the RCT leading to placebo effects and variation in the delivery of chemotherapy and radiochemotherapy.

**Articles:** A literature search was conducted revealing 13 articles (Please refer to appendix B) of which one meets inclusion criteria (studies involving histologically confirmed GBM, standard concomitant chemoradiation with Temozolomide, age >18 years with ≥ 70% on Karnofsky Performance Status (KPS) score and good renal and bone marrow function, received TTFields plus Temozolomide as maintenance therapy). The study on “Maintenance Therapy with tumor-treating fields plus temozolomide vs Temozolomide alone for Glioblastoma: A randomized clinical trial” will be critically appraised.

The use of Tumor Treating Fields (TTFields) plus Temozolomide as maintenance therapy for Glioblastoma multiforme (GBM) does meet the *Kaiser Permanente Medical Technology Assessment Criteria*.

## Introduction

Tumor treating fields (TTF) is a new treatment being studied for use in certain cancers. The therapy consists of low-level electrical currents that arise from small insulated electrodes placed on the skin surface. TTF is believed to cause cell death during a later stage of development. Currently this therapy is covered as one treatment option for people who have a deadly form of brain cancer called glioblastoma multiforme. People wear a helmet with small electrodes attached to the scalp for at least 18 hours per day during TTF therapy. This treatment requires pre-approval by the plan, and this policy describes when this treatment is covered. TTF is considered investigational for other types of cancer (therefore not covered), as there is not yet enough scientific data that shows it works for other diagnoses.

**Note:** The Introduction section is for your general knowledge and is not to be taken as policy coverage criteria. The rest of the policy uses specific words and concepts familiar to medical professionals. It is intended for providers. A provider can be a person, such as a doctor, nurse, psychologist, or dentist. A provider also can be a place where medical care is given, like a hospital, clinic, or lab. This policy informs them about when a service may be covered.

## Policy Coverage Criteria

Condition	Medical Necessity
<b>Glioblastoma- adjuvant therapy</b>	<p><b>Tumor treating fields (TTF) therapy to treat glioblastoma is medically necessary when ALL of the following are met:</b></p> <ul style="list-style-type: none"> <li>• The patient has completed debulking surgery or biopsy</li> </ul> <p><b>AND</b></p> <ul style="list-style-type: none"> <li>• The patient has completed radiation therapy</li> </ul> <p><b>AND</b></p> <ul style="list-style-type: none"> <li>• The patient is being treated with temozolmide</li> </ul> <p><b>AND</b></p> <ul style="list-style-type: none"> <li>• TTF therapy is begun within 7 weeks of the final radiation treatment</li> </ul>

Condition	Investigational
<b>Glioblastoma- for advanced or recurrent disease</b>	<b>Tumor treating fields therapy(TTF) to treat advanced or recurrent glioblastoma is considered investigational.</b>
<b>All other diagnoses</b>	<b>Tumor treating fields (TTF) is considered investigational for all other indications.</b>

## Coding

Code	Description
<b>HCPCS</b>	
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type

## Related Information

## Evidence Review

---

### Background

#### *Glioblastoma Multiforme*

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. They comprise approximately 15% of all brain and central nervous system tumors, and more than 50% of all tumors that arise from glial cells.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy.<sup>1</sup> According to the National Comprehensive Cancer Network, only a third of patients with GBM survive for 1 year and less than 5% live beyond 5 years.<sup>2</sup>

#### *Treatment of Glioblastoma Multiforme*

The primary treatment for initial GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea, or BCNU) impregnated wafer.<sup>2</sup> Depending on the patient's physical condition, adjuvant radiotherapy and/or chemotherapy (typically temozolomide) are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide.

No standard treatment exists for recurrent GBM. After these initial treatments, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab and bevacizumab combined with other chemotherapy such as irinotecan, BCNU/chloroethylnitrosourea (CCNU), or temozolomide. Temozolomide, nitrosourea, PCV (a combination of procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents have also been used.<sup>2</sup> External beam radiotherapy also may be used. Response rates in recurrent disease are less than 10%, and progression-free survival at 6 months is typically less than 20%.<sup>2,3</sup>

## ***Tumor Treating Fields Therapy***

TTF therapy is a new, noninvasive technology intended to treat GBM on an outpatient basis using electrical fields.<sup>3-5</sup> TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by two mechanisms: arrest of cell proliferation and destruction of cells while undergoing division.<sup>4,5</sup>

The NovoTTF-100A System has received marketing approval from the U.S. Food and Drug Administration to deliver TTF therapy. TTF therapy via the NovoTTF-100A System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes noninvasively attached to the patient's shaved scalp over the site of the tumor.<sup>3,4</sup> The device is used by the patient at home on a continuous basis (20-24 h/d) for the duration of treatment, which can last for several months. The device is covered under the DME benefit. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.<sup>3,4</sup>

## **Summary of Evidence**

For individuals who have progressive or recurrent glioblastoma multiforme (GBM) after initial or repeat surgery, radiotherapy, and/or chemotherapy who then receive tumor treatment fields (TTF) therapy as an alternative to standard chemotherapy, the evidence includes a randomized controlled trial (RCT) and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The published RCT reported no differences in outcomes between patients treated with TTF and with standard chemotherapy. This trial had several methodologic limitations. Comparisons that were made only included an active control of questionable efficacy, which might not reflect current standard of care. There was a high dropout rate (>20% of patients in each group were lost to follow-up) and, for the quality of life outcomes, only 25% of enrolled patients had complete data. The 2 nonrandomized studies were small and had limited validity due to differences in the patient populations treated with TTF and standard care. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have newly diagnosed GBM and receive TTF therapy as an adjunct to standard maintenance therapy following their initial treatment with surgery, radiotherapy, and/or chemotherapy, the evidence includes a single RCT. Relevant outcomes include overall survival, disease-specific survival, symptoms, functional outcomes, quality of life, and treatment-related morbidity. The single RCT reported that patients who received TTF treatment plus

temozolomide had longer progression-free survival (3.1 months) and overall survival (4.9 months) than patients who received temozolomide alone. However, the trial had methodologic limitations including the lack of a placebo control, differential dropout between groups, and the possibility of adherence bias for outcomes reported with per-protocol analysis. Further corroboration of these results is needed in high-quality RCTs. Although evidence is limited, NCCN has given this therapy a 2A rating. There are very few treatment options for this disease, and the side effect profile of TTF is much more tolerable to patients.

## Ongoing and Unpublished Clinical Trials

Some currently unpublished trials that might influence this review are listed in [Table 1](#).

**Table 1. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
<b>Ongoing</b>			
<a href="#">NCT01894061</a> <sup>a</sup>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	Dec 2017
<a href="#">NCT01756729</a> <sup>a</sup>	A Prospective, Non-randomized, Concurrent Control, Open Label, Post-approval Study of NovoTTF-100A in Recurrent GBM Patient	486	Jan 2018
<a href="#">NCT02743078</a> <sup>a</sup>	Phase II Trial Of Optune® Plus Bevacizumab In Bevacizumab-Refractory Recurrent Glioblastoma	85	Apr 2018
<a href="#">NCT01954576</a>	A Phase II Study of the NovoTTF-100A system, Enhanced by Genomic Analysis to Identify the Genetic Signature of Response in the Treatment of Recurrent Glioblastoma Multiforme	30	May 2018
<a href="#">NCT02663271</a> <sup>a</sup>	A Phase 2, Multi-center, Single Arm, Histologically Controlled Study Testing the Combination of TTFIELDS and Pulsed Bevacizumab Treatment in Patients With Bevacizumab-refractory Recurrent Glioblastoma	25	May 2018
<a href="#">NCT02893137</a> <sup>a</sup>	Phase 1 Enhancing Optune Therapy of Recurrent Glioblastoma Multiforme Using Targeted Surgical Skull Remodeling	15	Oct 2019

NCT No.	Trial Name	Planned Enrollment	Completion Date
<a href="#">NCT01925573</a> <sup>a</sup>	Proposed Pilot Study of Combined Optune+ Bevacizumab, and Hypofractionated Stereotactic Irradiation for Bevacizumab-Naive Recurrent Glioblastoma	27	Dec 2021

NCT: national clinical trial. <sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## Clinical Input From Physician Specialty Societies and Academic Medical Centers

While the various physician specialty societies and academic medical centers may provide appropriate reviewers who collaborate with and make recommendations during this process, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 3 physician specialty societies (one of which provided 6 responses and 2 of which provided 1 response each) and 1 academic medical center (total of 9 individual responses) while this policy was under review in 2016. There was majority support, but not consensus, for use of tumor treatment fields therapy as an adjunct to maintenance treatment following initial therapy for glioblastoma multiforme. There was mixed support for the use of tumor treatment fields as an alternative to chemotherapy in advanced or recurrent glioblastoma multiforme.

## Practice Guidelines and Position Statements

National Comprehensive Cancer Network guidelines on central nervous system cancers (v.1.2016)<sup>2</sup> include a recommendation for the treatment of glioblastoma. For the initial treatment of patients with glioblastoma with good performance status and either methylated or unmethylated or indeterminate MGMT promotor status, treatment with standard brain radiotherapy plus concurrent temozolomide and adjuvant temozolomide plus alternating electric currents therapy is a category 2A recommendation. Alternating electric currents therapy is only an option for patients with supratentorial disease. Consideration of alternating electric field therapy for recurrent glioblastoma is a 2B recommendation.

## Medicare National Coverage

There is no National Coverage Decision (NCD). In the absence of an NCD, coverage decisions are left to the discretion of local Medicare carriers.

## Regulatory Status

In April 2011, the NovoTTF-100A™ System (Novocure, Haifa, Israel; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process.<sup>7</sup> The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM [glioblastoma multiforme], following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."<sup>7</sup>

In September 2014, FDA approved Novocure's request to change its product name from NovoTTF-110A System to Optune®.<sup>8</sup>

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM.<sup>6</sup> The device was granted priority review status in May 2015 because there was no legally marketed alternative device currently available for the treatment of newly diagnosed GBM that represents a life-threatening condition.

The FDA-approved label reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune™ with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

Based on the 2011 approval Optune® is also approved for the treatment of recurrent GBM in the supratentorial region of the brain after receiving chemotherapy. The device is intended for use as a monotherapy, and as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

FDA product code: NZK.

## UTILIZATION MANAGEMENT POLICY

**TITLE:** ELECTRIC TUMOR TREATMENT FIELDS

**EFFECTIVE DATE:** November 16, 2016

*This policy was developed with input from specialists in neurosurgery, oncology, and radiation oncology and endorsed by the Medical Policy Committee.*

### IMPORTANT INFORMATION – PLEASE READ BEFORE USING THIS POLICY

*These services may or may not be covered by all Medica plans. Please refer to the member's plan document for specific coverage information. If there is a difference between this general information and the member's plan document, the member's plan document will be used to determine coverage. With respect to Medicare, Medicaid and MinnesotaCare members, this policy will apply unless these programs require different coverage. Members may contact Medica Customer Service at the phone number listed on their member identification card to discuss their benefits more specifically. Providers with questions about this Medica utilization management policy may call the Medica Provider Service Center toll-free at 1-800-458-5512.*

*Medica utilization management policies are not medical advice. Members should consult with appropriate health care providers to obtain needed medical advice, care and treatment.*

### PURPOSE

To promote consistency between reviewers in utilization management decision-making by providing the criteria that generally determine the medical necessity of electric tumor treatment fields (Optune System). The Coverage Issues box below outlines the process for addressing the needs of individuals who do not meet these criteria.

### BACKGROUND

#### I. Definitions

- A. **Electric Tumor Treatment Fields (ETTF or TTF)** technology applies low-intensity alternating electric fields to the brain to disrupt the division of cancer cells. The Optune system (formerly known as NovoTTF-100A) consists of four sets of insulated electrodes and a generator. The array attaches to the patient's shaved scalp and is connected to the generator by wires. The patient wears the device continuously (20-24 hours per day), for at least four weeks.
- B. **Glioblastoma** also known as GBM, glioblastoma multiforme, and grade IV astrocytoma, is a fast-growing type of central nervous system tumor that forms from glial (supportive) tissue of the brain and spinal cord. Glioblastoma usually occurs in adults and affects the brain more often than the spinal cord. Symptoms depend on tumor location and may include language deficits, numbness, weakness, headaches, seizures, nausea and vomiting, or confusion. It is most common in older individuals, with a median survival rate of approximately 15 months; five-year survival rate is approximately 4%. The exact cause of glioblastoma is not known.
- C. The **NovoTAL simulation software** may be used to determine the optimal location for placement of the transducer array, which is based on the patient's MRI scan, head size, and tumor location.
- D. The **supratentorial** region of the brain is located above the tentorium cerebelli (the arched fold of dura mater that covers the upper surface of the cerebellum and supports the occipital lobes of the cerebrum) and contains the cerebrum.

### MEDICAL NECESSITY CRITERIA

#### I. Indications for electric tumor treatment fields

Documentation in the medical records indicates that **all of the following** criteria are met:

- A. The member is at least 22 years old
- B. There is histologically-confirmed glioblastoma multiforme (GBM)
- C. The treatment is being provided by a certified Novo-TTF 100A System prescriber, and **one of the following**

are met:

1. There is concurrent treatment of new disease with temozolomide (TMZ), unless TMZ has been ineffective, not tolerated, or is contraindicated, OR
2. There is recurrent disease and the treatment used as monotherapy after other options have been exhausted.

II. Contraindications

**None of the following** are present:

- A. An active implantable medical device (e.g., deep brain stimulator, spinal cord stimulator, vagus nerve stimulator, pacemaker, defibrillator, programmable shunt)
- B. Skull defect
- C. Bullet fragment
- D. Known sensitivity to conductive hydrogels used with device transducer arrays
- E. Pregnancy.

COVERAGE ISSUES

1. Prior authorization **is required** for electric tumor treatment fields.
2. Coverage may vary according to the terms of the member's plan document.
3. Electric tumor treatment fields (Optune System) for all other indications, including the treatment of other malignant tumors, *is investigative, and therefore, not covered*.
4. For Medicare members, refer to the Medicare Coverage Database Search Page as applicable, at: <http://www.cms.hhs.gov/mcd/search.asp>
5. If the Medical Necessity and Coverage Criteria are met, Medica will authorize benefits within the limits in the member's plan document.
6. If it appears that the Medical Necessity and Coverage Criteria are not met, the individual's case will be reviewed by the medical director or an external reviewer. Practitioners are reminded of the appeals process in their Medica Provider Administrative Manual.

## Medi-Cal Update

Durable Medical Equipment and Medical Supplies | January 2016 | Bulletin 484

### 2. Updated Indications for HCPCS Code E0766

Effective for dates of service on or after February 1, 2016, the indications for the treatment of glioblastoma multiforme (GBM) with HCPCS code E0766 (electrical stimulation device used for cancer treatment, includes all accessories, any type) have been updated.

HCPCS code E0766 is indicated for the treatment of adult patients 22 years of age and older:

- With temozolomide for newly diagnosed, histologically confirmed supratentorial GBM following maximal debulking surgery, and completion of radiation therapy together with concomitant standard of care chemotherapy; or,
- With histologically or radiologically confirmed recurrent GBM in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy and an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

This information is reflected in the following provider manual(s):

Spinal cord stimulation (63655-63688) is not included on this line when paired with ICD-10-CM category G90.5  
Complex regional pain syndrome/reflex sympathetic dystrophy. Chemodenervation with botulinum toxin injection

**PRIORITIZED LIST OF HEALTH SERVICES**  
**JANUARY 1, 2018 (REVISED)**

(CPT 64642-64647) is included on this line for treatment of upper and lower limb spasticity (ICD-10-CM codes G24.02, G24.1, G35, G36.0, I69.03- I69.06 and categories G71, and G80-G83.) CPT codes 62320-3 are only included on Lines 71 and 292 for trials of antispasmodics in preparation for placement of a baclofen pump.

# STATEMENTS OF INTENT

#### STATEMENT OF INTENT 1: PALLIATIVE CARE

It is the intent of the Commission that palliative care services are covered for patients with a life-threatening or serious progressive illness to alleviate symptoms and improve quality of life.

Palliative care services should include culturally appropriate discussions and medical decision making aligned with patient's personal goals of therapy, assessment of symptom burden, assistance with advance care planning, care coordination, emotional, psychosocial and spiritual support for patients and their families. Palliative care services may be provided concurrently with life prolonging/curative treatments.

Some examples of services associated with an encounter for palliative care (ICD-10 Z51.5) that should be available to patients without regard to Prioritized List line placement:

- A) Inpatient palliative care consultations
  - 1) Hospital Care E&M (CPT 99218-99233)
- B) Outpatient palliative care consultations provided in either the office or home setting
  - 1) E&M Services (CPT 99201-99215)
  - 2) Transitional Care Management Services (CPT 99495-6)
  - 3) Advance Care Planning (CPT 99497-8)
  - 4) Chronic Care Management (CPT 99487-99490)
- C) Psychological support and grief counseling (CPT 99201-99215)
- D) Medical equipment and supplies for the management of symptomatic complications or support activities of daily living
- E) Medications or acupuncture to reduce pain and symptom burden
- F) Surgical procedures or therapeutic interventions to relieve pain or symptom burden

Other services associated with palliative care includes:

- A) Social Work
- B) Clinical Chaplain/ Spiritual Care
- C) Care Coordination

It is NOT the intent of the Commission that coverage for palliative care encompasses those treatments that seek to prolong life despite substantial burdens of treatment and limited chance of benefit. See Guideline Note 12 TREATMENT OF CANCER WITH LITTLE OR NO BENEFIT.

#### STATEMENT OF INTENT 2: DEATH WITH DIGNITY ACT

It is the intent of the Commission that services under ORS 127.800-127.897 (Oregon Death with Dignity Act) be covered for those that wish to avail themselves to those services. Such services include but are not limited to attending physician visits, consulting physician confirmation, mental health evaluation and counseling, and prescription medications.

#### STATEMENT OF INTENT 3: LOWER PRIORITY SERVICES

It is the intent of the Commission that therapies that exhibit one or more of the following characteristics generally be given low priority on the Prioritized List:

- A) Marginal or clinically unimportant benefit
- B) Unproven/no benefit
- C) Harms outweigh benefits
- D) very high cost in which the cost does not justify the benefit
- E) significantly greater cost compared to alternate therapies when both have similar benefit
- F) Significant budget impact that could affect the overall Prioritized List funding level

Where possible, the Commission prioritizes pairings of condition and treatment codes to reflect this lower priority, or simply does not pair a procedure code with one or more conditions if it exhibits one of these characteristics. This is, however, impractical in several circumstances:

- A) For diagnostic services appropriate for billing with a variety of diagnoses, including diagnoses representing signs and symptoms as well as diagnoses which otherwise appear above the funding line
- B) For ancillary services such as prescription drugs, supplies, physician-administered drugs or durable medical equipment and not identified by a CPT or HCPCS code appropriate for placement on the Prioritized List
- C) For procedure codes not appropriate for placement in the funded region of the list but which may be billed with many possible diagnoses, some of which are above the funding line while others may be below the funding line

In these circumstances, the HERC identifies the services in Guideline Notes 172 and 173, which are attached to Line 500 or Line 660 in order to make its intent transparent.

#### STATEMENT OF INTENT 4: ROLE OF THE PRIORITIZED LIST IN COVERAGE

The Commission makes its prioritization decisions based on the best available published evidence about treatments for each condition. The Prioritized List prioritizes health services according to their importance for the population served and the legislature determines where to place the funding line on the Prioritized List.

The Commission recognizes that a condition and treatment pairing above the funding line does not necessarily mean that the service will be covered by the Oregon Health Plan (OHP). There may be other restrictions that apply, such as the service not being medically necessary or appropriate for an individual member. Likewise, the absence of a treatment and condition pairing above the

**STATEMENT OF INTENT 4: ROLE OF THE PRIORITIZED LIST IN COVERAGE (CONT'D)**

funding line is not meant to be an absolute exclusion from coverage. Coverage may still be authorized under applicable federal and state laws, and Oregon's Medicaid State Plan and Waiver for an individual member. For example, OAR 410-141-0480 (Oregon Health Plan Benefit Package of Covered Services) includes services such as, but not limited to, the following:

- Diagnostic services, subject to the List's diagnostic guideline notes when applicable;
- Ancillary services (such as hospitalization, durable medical equipment, certain medications and anesthesia) provided for conditions appearing above the funding line, subject to the List's ancillary guideline notes when applicable; and
- Services paired with an unfunded condition which is causing or exacerbating a funded condition, the treatments for the funded condition are not working or contraindicated, and treatment of the unfunded condition would improve the outcome of treating the funded condition (the "Comorbidity Rule" OAR 410-141-0480(8)(a through b))

In addition, Oregon's 1115(a) Waiver includes coverage for services such as, but not limited to:

- Services on unfunded lines for children ages from birth through 1
- Services provided for a condition appearing in the funded region of the List in conjunction with federal requirements for Early and Periodic Screening, Diagnosis and Treatment (EPSDT) and Oregon's waiver

As a result, the Prioritized List must be used in conjunction with applicable OHP provisions found in federal and state laws, the State Plan and Waiver in coverage determination.

# PRACTICE GUIDELINES

GUIDELINE NOTES FOR ANCILLARY AND DIAGNOSTIC SERVICES  
NOT APPEARING ON THE JANUARY 1, 2018 PRIORITIZED LIST  
OF HEALTH SERVICES

GUIDELINE NOTES FOR HEALTH SERVICES  
THAT APPEAR ON THE JANUARY 1, 2018 PRIORITIZED LIST  
OF HEALTH SERVICES

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**ANCILLARY GUIDELINE A1, NERVE BLOCKS**

The Health Evidence Review Commission intends that single injection and continuous nerve blocks (CPT 64400-64450, 64461-64463, 64505-64530) should be covered services if they are required for successful completion of perioperative pain control for, or post-operative recovery from a covered operative procedure when the diagnosis requiring the operative procedure is also covered. Additionally, nerve blocks, are covered services for patients hospitalized with trauma, cancer, or intractable pain conditions, if the underlying condition is a covered diagnosis.

**ANCILLARY GUIDELINE A2, SELF-MONITORING OF BLOOD GLUCOSE IN DIABETES**

For patients with type 1 diabetes and those with type 2 diabetes using multiple daily insulin injections, home blood glucose monitors and related diabetic supplies are covered.

For patients with type 2 diabetes not requiring multiple daily insulin injections, 50 test strips and related supplies are covered at the time of diagnosis. For those who require diabetic medication that may result in hypoglycemia, up to 50 test strips per 90 days are covered. If there is an acute change in glycemic control or active diabetic medication adjustment, an additional 50 strips are covered.

All diabetic patients who are prescribed diabetic test strips should have a structured education and feedback program for self-monitoring of blood glucose.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**ANCILLARY GUIDELINE A3, IVC FILTERS FOR TRAUMA**

It is the intent of the Commission that inferior vena cava (IVC) filter placement (CPT 37191) and subsequent repositioning and removal (CPT 37192, 37193) are covered when medically indicated for hospitalized patients with severe trauma resulting in prolonged hospitalization.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**ANCILLARY GUIDELINE A4, SMOKING CESSATION AND ELECTIVE SURGICAL PROCEDURES**

Smoking cessation is required prior to elective surgical procedures for active tobacco users. Cessation is required for at least 4 weeks prior to the procedure and requires objective evidence of abstinence from smoking prior to the procedure.

Elective surgical procedures in this guideline are defined as surgical procedures which are flexible in their scheduling because they do not pose an imminent threat nor require immediate attention within 1 month. Reproductive (i.e. for contraceptive purposes), cancer-related and diagnostic procedures are excluded from this guideline.

The well-studied tests for confirmation of smoking cessation include cotinine levels and exhaled carbon monoxide testing. However, cotinine levels may be positive in nicotine replacement therapy (NRT) users, smokeless tobacco and e-cigarette users (which are not contraindications to elective surgery coverage). In patients using nicotine products aside from combustible cigarettes the following alternatives to urine cotinine to demonstrate smoking cessation may be considered:

- Exhaled carbon monoxide testing
- Anabasine or anatabine testing (NRT or vaping)

Certain procedures, such as lung volume reduction surgery, bariatric surgery, erectile dysfunction surgery, and spinal fusion have 6 month tobacco abstinence requirements. See Guideline Notes 8, 100, 112 and 159.

**DIAGNOSTIC GUIDELINE D1, NON-PRENATAL GENETIC TESTING GUIDELINE**

- A) Genetic tests are covered as diagnostic, unless they are listed below in section F1 as excluded or have other restrictions listed in this guideline. To be covered, initial screening (e.g. physical exam, medical history, family history, laboratory studies, imaging studies) must indicate that the chance of genetic abnormality is > 10% and results would do at least one of the following:
  - 1) Change treatment,
  - 2) Change health monitoring,
  - 3) Provide prognosis, or
  - 4) Provide information needed for genetic counseling for patient; or patient's parents, siblings, or children
- B) Pretest and posttest genetic counseling is required for presymptomatic and predisposition genetic testing. Pretest and posttest genetic evaluation (which includes genetic counseling) is covered when provided by a suitable trained health professional with expertise and experience in genetics.
  - 1) "Suitably trained" is defined as board certified or active candidate status from the American Board of Medical Genetics, American Board of Genetic Counseling, or Genetic Nursing Credentialing Commission.
- C) A more expensive genetic test (generally one with a wider scope or more detailed testing) is not covered if a cheaper (smaller scope) test is available and has, in this clinical context, a substantially similar sensitivity. For example, do not cover CFTR gene sequencing as the first test in a person of Northern European Caucasian ancestry because the gene panels are less expensive and provide substantially similar sensitivity in that context.

**DIAGNOSTIC GUIDELINE D1, NON-PRENATAL GENETIC TESTING GUIDELINE (CONT'D)**

- D) Related to genetic testing for patients with breast/ovarian and colon/endometrial cancer or other related cancers suspected to be hereditary, or patients at increased risk to due to family history.
- 1) Services are provided according to the Comprehensive Cancer Network Guidelines.
    - a) Lynch syndrome (hereditary colorectal, endometrial and other cancers associated with Lynch syndrome) services (CPT 81288, 81292-81300, 81317-81319, 81435, 81436) and familial adenomatous polyposis (FAP) services (CPT 81201-81203) should be provided as defined by the NCCN Clinical Practice Guidelines in Oncology. Genetic/Familial High-Risk Assessment: Colorectal V3.2017 (10/10/17). [www.nccn.org](http://www.nccn.org).
    - b) Breast and ovarian cancer syndrome genetic testing services (CPT 81162, 81211-81217) for women without a personal history of breast, ovarian and other associated cancers should be provided to high risk women as defined by the US Preventive Services Task Force or according to the NCCN Clinical Practice Guidelines in Oncology: Genetic/Familial High-Risk Assessment: Breast and ovarian. V1.2018 (10/3/17). [www.nccn.org](http://www.nccn.org).
    - c) Breast and ovarian cancer syndrome genetic testing services (CPT 81162, 81211-81217) for women with a personal history of breast, ovarian, and other associated cancers and for men with breast cancer should be provided according to the NCCN Clinical Practice Guidelines in Oncology. Genetic/Familial High-Risk Assessment: Breast and Ovarian. V1.2018 (10/3/17). [www.nccn.org](http://www.nccn.org).
    - d) PTEN (Cowden syndrome) services (CPT 81321-81323) should be provided as defined by the NCCN Clinical Practice Guidelines in Oncology. Colorectal Screening. V3.2017 (10/10/17). [www.nccn.org](http://www.nccn.org).
  - 2) Genetic counseling should precede genetic testing for hereditary cancer whenever possible.
    - a) Pre and post-test genetic counseling should be covered when provided by a suitable trained health professional with expertise and experience in cancer genetics. Genetic counseling is recommended for cancer survivors when test results would affect cancer screening.
      - i) "Suitably trained" is defined as board certified or active candidate status from the American Board of Medical Genetics, American Board of Genetic Counseling, or Genetic Nursing Credentialing Commission.
    - b) If timely pre-test genetic counseling is not possible for time-sensitive cases, appropriate genetic testing accompanied by pre- and post- test informed consent and post-test disclosure performed by a board-certified physician with experience in cancer genetics should be covered.
      - i) Post-test genetic counseling should be performed as soon as is practical.
  - 3) If the mutation in the family is known, only the test for that mutation is covered. For example, if a mutation for BRCA 1 has been identified in a family, a single site mutation analysis for that mutation is covered (CPT 81215), while a full sequence BRCA 1 and 2 (CPT 81211) analyses is not. There is one exception, for individuals of Ashkenazi Jewish ancestry with a known mutation in the family, the panel for Ashkenazi Jewish BRCA mutations is covered (CPT 81212).
  - 4) Costs for rush genetic testing for hereditary breast/ovarian and colon/endometrial cancer is not covered.
  - 5) Hereditary breast cancer-related disorders genomic sequence analysis panels (CPT 81432, 81433, 81479) are only included if the panel test
    - a) Includes at least 5 genes that the NCCN Clinical Practice Guidelines in Oncology - Genetic/Familial High-Risk Assessment: Colorectal V3.2017 (10/10/17) and/or NCCN Clinical Practice Guidelines in Oncology - Genetic/Familial High-Risk Assessment: Breast and Ovarian V1.2018 (10/3/17) include(s) with specific guidance on clinical management; and,
    - b) Includes no more than a reasonable number of genes (e.g. 40 genes total).
- E) Related to diagnostic evaluation of individuals with intellectual disability (defined as a full scale or verbal IQ < 70 in an individual > age 5), developmental delay (defined as a cognitive index <70 on a standardized test appropriate for children < 5 years of age), Autism Spectrum Disorder, or multiple congenital anomalies:
- 1) CPT 81228, Cytogenomic constitutional microarray analysis for copy number variants for chromosomal abnormalities: Cover for diagnostic evaluation of individuals with intellectual disability/developmental delay; multiple congenital anomalies; or, Autism Spectrum Disorder accompanied by at least one of the following: dysmorphic features including macro or microcephaly, congenital anomalies, or intellectual disability/developmental delay in addition to those required to diagnose Autism Spectrum Disorder.
  - 2) CPT 81229, Cytogenomic constitutional microarray analysis for copy number variants for chromosomal abnormalities; plus cytogenetic constitutional microarray analysis for single nucleotide polymorphism (SNP) variants for chromosomal abnormalities: Cover for diagnostic evaluation of individuals with intellectual disability/developmental delay; multiple congenital anomalies; or, Autism Spectrum Disorder accompanied by at least one of the following: dysmorphic features including macro or microcephaly, congenital anomalies, or intellectual disability/developmental delay in addition to those required to diagnose Autism Spectrum Disorder; only if (a) consanguinity and recessive disease is suspected, or (b) uniparental disomy is suspected, or (c) another mechanism is suspected that is not detected by the copy number variant test alone.
  - 3) CPT 81243, 81244, Fragile X genetic testing is covered for individuals with intellectual disability/developmental delay. Although the yield of Fragile X is 3.5-10%, this is included because of additional reproductive implications.
  - 4) A visit with the appropriate specialist (often genetics, developmental pediatrics, or child neurology), including physical exam, medical history, and family history is covered. Physical exam, medical history, and family history by the appropriate specialist, prior to any genetic testing is often the most cost-effective strategy and is encouraged.
- F) Related to other tests with specific CPT codes:
- 1) Certain genetic tests have not been found to have proven clinical benefit. These tests are listed in Guideline Note 173, INTERVENTIONS THAT HAVE NO CLINICALLY IMPORTANT BENEFIT OR HAVE HARMS THAT OUTWEIGH BENEFITS FOR CERTAIN CONDITIONS; UNPROVEN INTERVENTIONS
  - 2) The following tests are covered only if they meet the criteria in section A above AND the specified situations:
    - a) CPT 81205, BCKDHB (branched-chain keto acid dehydrogenase E1, beta polypeptide) (eg, Maple syrup urine disease) gene analysis, common variants (eg, R183P, G278S, E422X): Cover only when the newborn screening test is abnormal and serum amino acids are normal
    - b) Diagnostic testing for cystic fibrosis (CF)

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**DIAGNOSTIC GUIDELINE D1, NON-PRENATAL GENETIC TESTING GUIDELINE (CONT'D)**

- i) CFTR, cystic fibrosis transmembrane conductance regulator tests. CPT 81220, 81222, 81223: For infants with a positive newborn screen for cystic fibrosis or who are symptomatic for cystic fibrosis, or for clients that have previously been diagnosed with cystic fibrosis but have not had genetic testing, CFTR gene analysis of a panel containing at least the mutations recommended by the American College of Medical Genetics\* (CPT 81220) is covered. If two mutations are not identified, CFTR full gene sequencing (CPT 81223) is covered. If two mutations are still not identified, duplication/deletion testing (CPT 81222) is covered. These tests may be ordered as reflex testing on the same specimen.
- c) Carrier testing for cystic fibrosis
  - i) CFTR gene analysis of a panel containing at least the mutations recommended by the American College of Medical Genetics\* (CPT 81220) is covered once in a lifetime.
- d) CPT 81224, CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; intron 8 poly-T analysis (eg, male infertility): Covered only after genetic counseling.
- e) CPT 81240, F2 (prothrombin, coagulation factor II) (eg, hereditary hypercoagulability) gene analysis, 20210G>A variant: Factor 2 20210G>A testing should not be covered for adults with idiopathic venous thromboembolism; for asymptomatic family members of patients with venous thromboembolism and a Factor V Leiden or Prothrombin 20210G>A mutation; or for determining the etiology of recurrent fetal loss or placental abruption.
- f) CPT 81241, F5 (coagulation Factor V) (eg, hereditary hypercoagulability) gene analysis, Leiden variant: Factor V Leiden testing should not be covered for: adults with idiopathic venous thromboembolism; for asymptomatic family members of patients with venous thromboembolism and a Factor V Leiden or Prothrombin 20210G>A mutation; or for determining the etiology of recurrent fetal loss or placental abruption.
- g) CPT 81247, G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; common variant(s) (eg, A, A-) should only be covered
  - i) After G6PD enzyme activity testing is done and found to be normal; AND either
    - (a) There is an urgent clinical reason to know if a deficiency is present, e.g. in a case of acute hemolysis; OR
    - (b) In situations where the enzyme activity could be unreliable, e.g. female carrier with extreme Lyonization.
- h) CPT 81248, G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; known familial variant(s) is only covered when the information is required for genetic counseling.
- i) CPT 81249, G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; full gene sequence is only covered
  - i) after G6PD enzyme activity has been tested, and
  - ii) the requirements under CPT 81247 above have been met, and
  - iii) common variants (CPT 81247) have been tested for and not found.
- j) CPT 81256, HFE (hemochromatosis) (eg, hereditary hemochromatosis) gene analysis, common variants (eg, C282Y, H63D): Covered for diagnostic testing of patients with elevated transferrin saturation or ferritin levels. Covered for predictive testing ONLY when a first degree family member has treatable iron overload from HFE.
- k) CPT 81221, SERPINA1 (serpin peptidase inhibitor, clade A, alpha-1 antiproteinase, antitrypsin, member 1) (eg, alpha-1-antitrypsin deficiency), gene analysis, common variants (eg, \*S and \*Z): The alpha-1-antitrypsin protein level should be the first line test for a suspected diagnosis of AAT deficiency in symptomatic individuals with unexplained liver disease or obstructive lung disease that is not asthma or in a middle age individual with unexplained dyspnea. Genetic testing of the alpha-1 phenotype test is appropriate if the protein test is abnormal or borderline. The genetic test is appropriate for siblings of people with AAT deficiency regardless of the AAT protein test results.
- l) CPT 81415-81416, exome testing: A genetic counseling/geneticist consultation is required prior to ordering test
- m) CPT 81430-81431, Hearing loss (eg, nonsyndromic hearing loss, Usher syndrome, Pendred syndrome); genomic sequence analysis panel: Testing for mutations in GJB2 and GJB6 need to be done first and be negative in non-syndromic patients prior to panel testing.
- n) CPT 81440, 81460, 81465, mitochondrial genome testing: A genetic counseling/geneticist or metabolic consultation is required prior to ordering test.
- o) CPT 81412 Ashkenazi Jewish carrier testing panel: panel testing is only covered when the panel would replace and would be similar or lower cost than individual gene testing including CF carrier testing.

\* American College of Medical Genetics Standards and Guidelines for Clinical Genetics Laboratories. 2008 Edition, Revised 3/2011 and found at <https://www.acmg.net/StaticContent/SGs/CFTR%20Mutation%20Testing.pdf>.

**DIAGNOSTIC GUIDELINE D2, IMPLANTABLE CARDIAC LOOP RECORDERS**

Use of an implantable cardiac loop recorder (ICLR) is a covered service only when the patient meets all of the following criteria:

- 1) The evaluation is for recurrent transient loss of consciousness (TLoC); and
- 2) A comprehensive evaluation including 30 days of noninvasive ambulatory cardiac monitoring did not demonstrate a cause of the TLoC; and
- 3) A cardiac arrhythmia is suspected to be the cause of the TLoC; and
- 4) There is a likely recurrence of the TLoC within the battery longevity of the device.

ICLRs are not a covered service for evaluation of cryptogenic stroke or any other indication.

**DIAGNOSTIC GUIDELINE D3, ECHOCARDIOGRAMS WITH CONTRAST FOR CARDIAC CONDITIONS OTHER THAN CARDIAC ANOMALIES**

Need for contrast with an echocardiogram should be assessed and, if indicated, implemented at the time of the original ECHO and not as a separate procedure.

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**DIAGNOSTIC GUIDELINE D4, ADVANCED IMAGING FOR LOW BACK PAIN**

In patients with non-specific low back pain and no “red flag” conditions [see Table D4], imaging is not a covered service; otherwise work up is covered as shown in the table. Repeat imaging is only covered when there is a substantial clinical change (e.g. progressive neurological deficit) or new clinical indication for imaging (i.e. development of a new red flag condition). Repeat imaging for acute exacerbations of chronic radiculopathic pain is not covered.

Electromyography (CPT 96002-4) is not covered for non-specific low back pain.

**Table D4**  
**Low Back Pain - Potentially Serious Conditions (“Red Flags”) and Recommendations for Initial Diagnostic Work-up**

Possible cause	Key features on history or physical examination	Imaging <sup>1</sup>	Additional studies <sup>1</sup>
Cancer	<ul style="list-style-type: none"> <li>History of cancer with new onset of LBP</li> </ul>	MRI	ESR
	<ul style="list-style-type: none"> <li>Unexplained weight loss</li> <li>Failure to improve after 1 month</li> <li>Age &gt;50 years</li> <li>Symptoms such as painless neurologic deficit, night pain or pain increased in supine position</li> </ul>	Lumbosacral plain radiography	
	<ul style="list-style-type: none"> <li>Multiple risk factors for cancer present</li> </ul>	Plain radiography or MRI	
Spinal column infection	<ul style="list-style-type: none"> <li>Fever</li> <li>Intravenous drug use</li> <li>Recent infection</li> </ul>	MRI	ESR and/or CRP
Cauda equina syndrome	<ul style="list-style-type: none"> <li>Urinary retention</li> <li>Motor deficits at multiple levels</li> <li>Fecal incontinence</li> <li>Saddle anesthesia</li> </ul>	MRI	None
Vertebral compression fracture	<ul style="list-style-type: none"> <li>History of osteoporosis</li> <li>Use of corticosteroids</li> <li>Older age</li> </ul>	Lumbosacral plain radiography	None
Ankylosing spondylitis	<ul style="list-style-type: none"> <li>Morning stiffness</li> <li>Improvement with exercise</li> <li>Alternating buttock pain</li> <li>Awakening due to back pain during the second part of the night</li> <li>Younger age</li> </ul>	Anterior-posterior pelvis plain radiography	ESR and/or CRP, HLA-B27
Nerve compression/ disorders (e.g. herniated disc with radiculopathy)	<ul style="list-style-type: none"> <li>Back pain with leg pain in an L4, L5, or S1 nerve root distribution present &lt; 1 month</li> <li>Positive straight-leg-raise test or crossed straight-leg-raise test</li> </ul>	None	None
	<ul style="list-style-type: none"> <li>Radiculopathic signs<sup>2</sup> present &gt;1 month</li> <li>Severe/progressive neurologic deficits (such as foot drop), progressive motor weakness</li> </ul>	MRI <sup>3</sup>	Consider EMG/NCV
Spinal stenosis	<ul style="list-style-type: none"> <li>Radiating leg pain</li> <li>Older age</li> <li>Pain usually relieved with sitting (Pseudoclaudication a weak predictor)</li> </ul>	None	None
	<ul style="list-style-type: none"> <li>Spinal stenosis symptoms present &gt;1 month</li> </ul>	MRI <sup>3</sup>	Consider EMG/NCV

<sup>1</sup>Level of evidence for diagnostic evaluation is variable

<sup>2</sup>Radiculopathic signs are defined for the purposes of this guideline as the presence of any of the following:

- A) Markedly abnormal reflexes
- B) Segmental muscle weakness
- C) Segmental sensory loss
- D) EMG or NCV evidence of nerve root impingement
- E) Cauda equina syndrome,
- F) Neurogenic bowel or bladder
- G) Long tract abnormalities

<sup>3</sup>Only if patient is a potential candidate for surgery

Red Flag: Red flags are findings from the history and physical examination that may be associated with a higher risk of serious disorders.

CRP = C-reactive protein; EMG = electromyography; ESR = erythrocyte sedimentation rate; MRI = magnetic resonance imaging; NCV = nerve conduction velocity.

Extracted and modified from Chou R, Qaseem A, Snow V, et al: *Diagnosis and Treatment of Low Back Pain: A Joint Clinical Practice Guideline from the American College of Physicians and the American Pain Society*. Ann Intern Med. 2007; 147:478-491.

#### DIAGNOSTIC GUIDELINE D4, ADVANCED IMAGING FOR LOW BACK PAIN (CONT'D)

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### DIAGNOSTIC GUIDELINE D5, NEUROIMAGING FOR HEADACHE

Neuroimaging is not covered in patients with a defined tension or migraine type of headache, or a variation of their usual headache (e.g. more severe, longer in duration, or not responding to drugs).

Neuroimaging is covered for headache when a red flag\* is present.

\*The following represent red flag conditions for underlying abnormality with headache:

- A) New onset or change in headache in patients who are aged over 50
- B) Thunderclap headache: rapid time to peak headache intensity (seconds to 5 minutes)
- C) Focal neurological symptoms (e.g. limb weakness, lack of coordination, numbness or tingling)
- D) Non-focal neurological symptoms (e.g altered mental status, dizziness)
- E) Abnormal neurological examination
- F) Headache that changes with posture
- G) Headache wakening the patient up (Nota bene migraine is the most frequent cause of morning headache)
- H) Headache precipitated by physical exertion or valsalva maneuver (e.g. coughing, laughing, straining)
- I) Patients with risk factors for cerebral venous sinus thrombosis
- J) Jaw claudication
- K) Nuchal rigidity
- L) New onset headache in a patient with a history of human immunodeficiency virus (HIV) infection
- M) New onset headache in a patient with a history of cancer
- N) Cluster headache, paroxysmal hemicrania, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT), or short-lasting unilateral neuralgiform headache attacks with cranial autonomic features (SUNA).

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### DIAGNOSTIC GUIDELINE D6, BREAST CANCER SCREENING IN ABOVE-AVERAGE RISK WOMEN

Annual screening mammography and annual screening MRI are covered only for women at above-average risk of breast cancer. This coverage, beginning at 30 years of age, includes women who have one or more of the following:

- Greater than 20% lifetime risk of breast cancer
- BRCA1 or BRCA2 gene mutation, or who have not been tested for BRCA but have a first-degree relative who is a BRCA carrier
- A personal history or a first-degree relative diagnosed with Bannayan-Riley-Ruvalcaba syndrome, Cowden syndrome, or Li-Fraumeni syndrome
- Other germline gene mutations known to confer a greater than 20% lifetime risk of breast cancer

For women with a history of high dose chest radiation ( $\geq 20$  Gray) before the age of 30, annual screening MRI and annual screening mammography are covered beginning 8 years after radiation exposure or at age 25, whichever is later.

For women with both a personal history and a family history of breast cancer, annual mammography, annual breast MRI and annual breast ultrasound are covered.

For women with increased breast density, supplemental screening with breast ultrasound, MRI, or digital breast tomosynthesis is not covered.

Breast PET-CT scanning and breast-specific gamma imaging are not covered for breast cancer screening.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### DIAGNOSTIC GUIDELINE D7, NEUROIMAGING IN DEMENTIA

Neuroimaging is covered:

- A) To rule out reversible causes of dementia (tumors, normal pressure hydrocephalus and chronic subdural hematoma) via structural neuroimaging only

Neuroimaging is not covered:

- A) For screening of asymptomatic patients for dementia
- B) To predict progression of the risk of developing dementia in patients with mild cognitive impairment
- C) For screening, diagnosis, or monitoring of dementia, with functional neuroimaging (PET, SPECT or fMRI)

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**DIAGNOSTIC GUIDELINE D8, DIAGNOSTIC TESTING FOR OBSTRUCTIVE SLEEP APNEA (OSA) IN ADULTS**

Type I PSG is covered when used to aid the diagnosis of OSA in patients who have clinical signs and symptoms indicative of OSA if performed attended in a sleep lab facility.

OHP clients should have access to least one of the alternatives listed below:

- 1) Type II or Type III sleep testing devices when used to aid the diagnosis of OSA in patients who have clinical signs and symptoms indicative of OSA if performed unattended in or out of a sleep lab facility or attended in a sleep lab facility.
- 2) Type IV sleep testing devices measuring three or more channels, one of which is airflow, when used to aid the diagnosis of OSA in patients who have signs and symptoms indicative of OSA if performed unattended in or out of a sleep lab facility or attended in a sleep lab facility.
- 3) Sleep testing devices measuring three or more channels that include actigraphy, oximetry, and peripheral arterial tone, when used to aid the diagnosis of OSA in patients who have signs and symptoms indicative of OSA if performed unattended in or out of a sleep lab facility or attended in a sleep lab facility.

CPAP titration should be performed as part of the diagnostic study, if possible.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D9, MRI FOR BREAST CANCER DIAGNOSIS**

In women with recently diagnosed breast cancer, preoperative or contralateral MRI of the breast is not a covered service.

**DIAGNOSTIC GUIDELINE D10, MRI IN MULTIPLE SCLEROSIS**

MRI is a diagnostic test for multiple sclerosis and should not be used for routine monitoring of disease.

MRI may be considered in the following circumstances:

- A) Suspected drug failure in the setting of clinical relapse in patients with objective changes in neurological status or documented new clinical symptoms such as urinary urgency or cognitive changes
- B) Evaluation of a clear objective progression in clinical symptoms in patients with previously relapsing disease to rule out ongoing inflammatory disease when conversion to secondary progressive MS is suspected
- C) Patients who require enhanced pharmacovigilance, including
  - 1) Yearly monitoring for patients treated with natalizumab who are JCV seropositive
  - 2) One MRI for patients who switch from natalizumab to other therapeutics (including fingolimod, alemtuzumab and dimethyl fumarate) one year after the switch from natalizumab

**DIAGNOSTIC GUIDELINE D11, MRI OF THE SPINE (CERVICAL AND THORACIC)**

MRI of the cervical and thoracic spine is covered in the following situations:

- 1) Recent onset of major or progressive neurologic deficit (objective evidence of markedly abnormal reflexes, dermatomal muscle weakness, dermatomal sensory loss, EMG or NCV evidence of nerve root impingement), suspected cauda equina syndrome (loss of bowel or bladder control or saddle anesthesia), or neurogenic claudication in patients who are potential candidates for surgery;
- 2) Clinical or radiological suspicion of neoplasm; or,
- 3) Clinical or radiological suspicion of infection.

**DIAGNOSTIC GUIDELINE D12, UPPER ENDOSCOPY FOR GERD OR DYSPEPSIA SYMPTOMS**

Upper endoscopy for uninvestigated dyspepsia or GERD symptoms is covered for:

Patients less than 50 years of age with persistent symptoms following advice on lifestyle modifications and completion of an appropriate course of twice daily PPI therapy or an H. pylori test and treat protocol.

Patients 50 years of age and older

Patients with "alarm symptoms" including, but not limited to, iron deficiency anemia or weight loss

Upper endoscopy is not covered for patients with previous upper endoscopy with non-malignant findings (other than Barrett's esophagus) in the absence of significant new symptoms.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D13, SCREENING FOR CAROTID ARTERY STENOSIS**

Screening for carotid artery stenosis (CPT 93880) in the general primary care population is not a covered service.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D14, LUNG CANCER SCREENING**

Low dose computed tomography is included for annual screening for lung cancer in persons aged 55 to 80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years. Screening should be discontinued once a

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**DIAGNOSTIC GUIDELINE D14, LUNG CANCER SCREENING (CONT'D)**

person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery. Current smokers should be offered evidence based smoking cessation interventions.

**DIAGNOSTIC GUIDELINE D15, COMPUTER-AIDED MAMMOGRAPHY**

Computer-aided mammography is not intended to be a covered service.

**DIAGNOSTIC GUIDELINE D16, OSTEOPOROSIS SCREENING AND MONITORING IN ADULTS**

Osteoporosis screening by dual-energy X-ray absorptiometry (DXA) is covered only for women aged 65 or older, and for men or younger women whose 10-year risk of major osteoporotic fracture is equal to or greater than 9.3 percent.

Fracture risk should be assessed by the World Health Organization's FRAX tool or similar instrument.

Routine osteoporosis screening by DXA is not covered for men.

The frequency of subsequent monitoring for development of osteoporosis should not be based on DXA scores alone. If rapid change in bone density is expected, more frequent DXA scanning is appropriate (for example, in patients taking glucocorticoids, those with a history of rapid weight loss, those with medical conditions that could result in secondary osteoporosis, etc.).

If there has been no significant change in an individual's risk factors, monitoring by repeat DXA scanning is covered only at the following frequencies:

- once every two years for those with osteoporosis or advanced osteopenia (T-score of -2.00 or lower)
- once every four years for moderate osteopenia (T-score between -1.50 and -1.99)
- once every ten years for mild osteopenia (T-score between -1.01 and -1.49).
- once every fifteen years for those with normal bone density.

Repeat testing is only covered if the results will influence clinical management. For purposes of monitoring osteoporosis medication therapy, testing at intervals of less than two years is not covered.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D17, PRENATAL GENETIC TESTING**

The following types of prenatal genetic testing and genetic counseling are covered for pregnant women:

- A) Genetic counseling (CPT 96040, HPCPS S0265) for high risk women who have family history of inheritable disorder or carrier state, ultrasound abnormality, previous pregnancy with aneuploidy, or elevated risk of neural tube defect.
- B) Genetic counseling (CPT 96040, HPCPS S0265) prior to consideration of chorionic villus sampling (CVS), amniocentesis, microarray testing, Fragile X, and spinal muscular atrophy screening
- C) Validated questionnaire to assess genetic risk in all pregnant women
- D) Screening high risk ethnic groups for hemoglobinopathies (CPT 83020, 83021)
- E) Screening for aneuploidy with any of five screening strategies [first trimester (nuchal translucency, beta-HCG and PAPP-A), integrated, serum integrated, stepwise sequential, and contingency] (CPT 76813, 76814, 81508-81511)
- F) Cell free fetal DNA testing (CPT 81420, 81507) for evaluation of aneuploidy in women who have an elevated risk of a fetus with aneuploidy (maternal age >34, family history or elevated risk based on screening).
- G) Ultrasound for structural anomalies between 18 and 20 weeks gestation (CPT 76811, 76812)
- H) CVS or amniocentesis (CPT 59000, 59015, 82106, 88235, 88267, 88269, 88280, 88285) for a positive aneuploidy screen, maternal age >34, fetal structural anomalies, family history of inheritable chromosomal disorder or elevated risk of neural tube defect.
- I) Array CGH (CPT 81228, 81229) when major fetal congenital anomalies are apparent on imaging, or with normal imaging when array CGH would replace karyotyping performed with CVS or amniocentesis in #8 above.
- J) FISH testing (CPT 88271, 88275) only if karyotyping is not possible due a need for rapid turnaround for reasons of reproductive decision-making (i.e. at 22w4d gestation or beyond)
- K) Screening for Tay-Sachs carrier status (CPT 81255) in high risk populations. First step is hex A, and then additional DNA analysis in individuals with ambiguous Hex A test results, suspected variant form of TSD or suspected pseudodeficiency of Hex A
- L) Screening for cystic fibrosis carrier status once in a lifetime (CPT 81220-81224)
- M) Screening for fragile X status (CPT 81243, 81244) in patients with a personal or family history of
  - a. fragile X tremor/ataxia syndrome
  - b. premature ovarian failure
  - c. unexplained early onset intellectual disability
  - d. fragile X intellectual disability
  - e. unexplained autism through the pregnant woman's maternal line
- N) Screening for spinal muscular atrophy (CPT 81401) once in a lifetime
- O) Screening those with Ashkenazi Jewish heritage for Canavan disease (CPT 81200), familial dysautonomia (CPT 81260), and Tay-Sachs carrier status (CPT 81255). Ashkenazi Jewish carrier panel testing (CPT 81412) is covered if the panel would replace and would be of similar or lower cost than individual gene testing including CF carrier testing.
- P) Expanded carrier screening only for those genetic conditions identified above

The following genetic screening tests are not covered:

3-22-2018 (Includes 1-5-2018 Revisions)

Page AD-8

ANCILLARY/DIAGNOSTIC GUIDELINE NOTES FOR THE  
JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

**DIAGNOSTIC GUIDELINE D17, PRENATAL GENETIC TESTING (CONT'D)**

- A) Serum triple screen
- B) Screening for thrombophilia in the general population or for recurrent pregnancy loss
- C) Expanded carrier screening which includes results for conditions not explicitly recommended for coverage

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D18, ADVANCED IMAGING FOR STAGING OF PROSTATE CANCER**

MRI is covered for men with histologically proven prostate cancer if knowledge of the T or N stage could affect management. CT of the pelvis is covered only when MRI is contraindicated.

Radionuclide bone scanning is not covered in men with low risk localized prostate cancer. Low risk is defined as PSA <10 ng/ml and Gleason score ≤6 and clinical stage T1-T2a.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D19, SPECT**

SPECT (CPT 78451, 78452) is not covered for screening for coronary artery disease in asymptomatic patients.

Stress SPECT (78451, 78452 in conjunction with stress testing) is only covered for diagnosis or risk stratification of coronary artery disease when a stress ECHO is contraindicated, is unavailable or would provide suboptimal imaging (i.e. pre-existing cardiomyopathy, baseline regional wall motion abnormalities, left bundle branch block, paced rhythm, unsuitable acoustic windows due to body habitus, or inability to exercise with inability to utilize dobutamine.)

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**DIAGNOSTIC GUIDELINE D20, OPHTHALMOLOGY DIAGNOSTIC VISITS**

Ophthalmology diagnostic visits (CPT 92002, 92004, 92012, 92014, 92081-92083, 92100, 92140, 92133, 92134) are covered for the evaluation of serious eye symptoms such as sudden vision loss or eye pain.

**DIAGNOSTIC GUIDELINE D21, PHARMACOGENETICS TESTING FOR PSYCHIATRIC MEDICATION MANAGEMENT**

Pharmacogenetics testing for management of psychiatric medications is not a covered service.

# PRACTICE GUIDELINES

GUIDELINE NOTES FOR ANCILLARY AND DIAGNOSTIC SERVICES  
NOT APPEARING ON THE JANUARY 1, 2018 PRIORITIZED LIST  
OF HEALTH SERVICES

GUIDELINE NOTES FOR HEALTH SERVICES  
THAT APPEAR ON THE JANUARY 1, 2018 PRIORITIZED LIST  
OF HEALTH SERVICES

**GUIDELINE NOTE 1, ROUTINE CERVICAL CANCER SCREENING***Line 3*

Cervical cancer screening is covered on Line 3 for women:

Age group in years	Type of screening covered	Frequency
<21	None	Never
21-29	Cytology alone Mandatory HPV testing (87620-87621) is not covered for women age 21-29	Every 3 years
30-65	Co-testing* or cytology alone	Co-testing every 5 years Cytology alone every 3 years
>65	None Unless adequate screening** has not been achieved, or it is <20 years after regression or appropriate management of a high-grade precancerous lesion	Never
Women who have had a hysterectomy with removal of cervix for non cervical cancer related reasons (i.e. other than high grade precancerous lesion, CIN 2 or 3, or cervical cancer)	None	Never
Women who have abnormal testing	Per ASCCP*** Guideline, until indicated to resume routine screening	Per ASCCP Guideline, until indicated to resume routine screening

\*Co-testing is defined as simultaneous cytology and mandatory HPV testing.

\*\* Adequate screening is defined as 3 consecutive negative cytology results or 2 consecutive negative HPV results within 10 years of the cessation of screening, with the most recent test occurring within 5 years.

\*\*\* American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology guideline (Saslow 2012)

Women who have received a diagnosis of a high-grade precancerous cervical lesion or cervical cancer, women with in utero exposure to diethylstilbestrol, or women who are immunocompromised (such as those who are HIV positive) are intended to have screening more frequently than delineated in this guideline.

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 2, FETOSCOPIC SURGERY***Line 1*

Fetal surgery is only covered for the following conditions: repair of urinary tract obstructions via placement of a urethral shunt, repair of congenital cystic adenomatoid malformation, repair of extralobal pulmonary sequestration, repair of sacrococcygeal teratoma, and therapy for twin-twin transfusion syndrome.

Fetoscopic repair of urinary tract obstruction (S2401) is only covered for placement of a urethral shunt. Fetal surgery for cystic adenomatoid malformation of the lung, extralobal pulmonary sequestration and sacrococcygeal teratoma must show evidence of developing hydrops fetalis.

Certification of laboratory required (76813-76814).

**GUIDELINE NOTE 3, PROPHYLACTIC TREATMENT FOR PREVENTION OF BREAST CANCER IN HIGH RISK WOMEN***Line 191*

Bilateral prophylactic breast removal and/or oophorectomy are included on Line 191 for women without a personal history of invasive breast cancer who meet the criteria in the NCCN Clinical Practice Guidelines in Oncology. Breast Cancer Risk Reduction. V.1.2016 (2/23/16). [www.nccn.org](http://www.nccn.org). Prior to surgery, women without a personal history of breast cancer must have a genetics consultation as defined in section A2 of the DIAGNOSTIC GUIDELINE D1, NON-PRENATAL GENETIC TESTING GUIDELINE.

Contralateral prophylactic mastectomy is included on Line 191 for women with a personal history of breast cancer.

**GUIDELINE NOTE 4, TOBACCO DEPENDENCE, INCLUDING DURING PREGNANCY***Lines 1,5*

Pharmacotherapy (including varenicline, bupropion and all five FDA-approved forms of nicotine-replacement therapy) and behavioral counseling are included on this line, alone or in combination, for at least two quit attempts per year. At least two quit attempts per year

#### GUIDELINE NOTE 4, TOBACCO DEPENDENCE, INCLUDING DURING PREGNANCY (CONT'D)

must be provided without prior authorization, and each attempt can include both pharmacotherapy and behavioral counseling. Combination drug therapy (i.e. two forms of NRT or NRT plus bupropion) is also included with each quit attempt without prior authorization. However, nicotine inhalers and sprays may be subject to prior authorization.

A minimum of four counseling sessions of at least 10 minutes each (group or individual, telephonic or in person) are included for each quit attempt. More intensive interventions and group therapy are likely to be the most effective behavioral interventions. During pregnancy, additional intensive behavioral counseling is strongly encouraged. All tobacco cessation interventions during pregnancy are not subject to quantity or duration limits.

Inclusion on this line follows the minimum standard criteria as defined in the Oregon Public Health Division "Standard Tobacco Cessation Coverage" (based on the Patient Protection and Affordable Care Act), available here:

[http://www.oregon.gov/oha/PH/PREVENTIONWELLNESS/TOBACCO/TOBACCO/DOCUMENTS/tob\\_cessation\\_coverage\\_standards.pdf](http://www.oregon.gov/oha/PH/PREVENTIONWELLNESS/TOBACCO/TOBACCO/DOCUMENTS/tob_cessation_coverage_standards.pdf). The USPSTF has also made "A" recommendations for screening, counseling, and treatment of pregnant and nonpregnant adults, included in Guideline Note 106.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### GUIDELINE NOTE 5, OBESITY AND OVERWEIGHT

*Line 320*

Medical treatment of overweight (with known cardiovascular risk factors) and obesity in adults is limited to intensive counseling on nutrition and physical activity, provided by health care professionals. Intensive counseling is defined as face-to-face contact more than monthly. A multidisciplinary team is preferred, but a single clinician could also deliver intensive counseling in primary care or other settings.

Intensive counseling visits are included on this line for 6 months. Intensive counseling visits may continue for an additional 6 months (up to 12 months) as long as there is evidence of continued weight loss or improvement in cardiovascular risk factors based on the intervention. Maintenance visits at the conclusion of the intensive treatment are included on this line no more than monthly after this intensive counseling period. The characteristics of effective behavioral interventions include: high intensity programs; multicomponent (including at a minimum diet and exercise), group-based commercial programs; Mediterranean diet; and the following sub-elements -- calorie counting, contact with a dietician, and comparison to peers.

Known cardiovascular risk factors in overweight persons for which this therapy is effective include: hypertension, dyslipidemia, prediabetes, or the metabolic syndrome.

Medical treatment of obesity in children is limited to comprehensive, intensive behavioral interventions. For treatment of children up to 12 years old, interventions may be targeted only to parents, or to both parents and children.

Pharmacological treatments and devices (e.g. gastric balloons, duodenal jejunal bypass liners, and vagus nerve blocking devices) for obesity are not intended to be included as services on this line or any other line on the Prioritized List.

#### GUIDELINE NOTE 6, REHABILITATIVE AND HABILITATIVE THERAPIES

*Lines 31,46,57,68,71,72,74,81,91,92,131,132,136,150,153,160,178,183,184,196,197,201,202,208,255,257,272,285,287,292,300,301,309,317,341,345,348,355,356,359,376,377,400,407,415,417,421,422,430,441,453,461,464,465,476,484,495,507,553,556,569,586,605*

The quantitative limits in this guideline note do not apply to mental health or substance abuse conditions.

A total of 30 visits per year of rehabilitative therapy and a total of 30 visits per year of habilitative therapy (physical, occupational and speech therapy) are included on these lines when medically appropriate. Additional visits, not to exceed 30 visits per year of rehabilitative therapy and 30 visits per year of habilitative therapy, may be authorized in cases of a new acute injury, surgery, or other significant change in functional status. Children under age 21 may have additional visits authorized beyond these limits if medically appropriate.

Physical, occupational and speech therapy are only included on these lines when the following criteria are met:

- A) therapy is provided by a licensed physical therapist, occupational therapist, speech language pathologist, physician, or other practitioner licensed to provide the therapy,
- B) there is objective, measurable documentation of clinically significant progress toward the therapy plan of care goals and objectives,
- C) the therapy plan of care requires the skills of a medical provider, and
- D) the client and/or caregiver cannot be taught to carry out the therapy regimen independently.

No limits apply while in a skilled nursing facility for the primary purpose of rehabilitation, an inpatient hospital or an inpatient rehabilitation unit.

Spinal cord injuries, traumatic brain injuries, or cerebral vascular accidents are not subject to the visit limitations during the first year after an acute injury.

**GUIDELINE NOTE 7, ERYTHROPOIESIS-STIMULATING AGENT (ESA) GUIDELINE**

Lines 12,59,93,95,112-116,126,133,135,157,158,161,163,179,191,200,201,209,211,215,216,218,230,235,238,239,259-263,271,276,286-288,294,295,314-316,329,396,397,400,418,433,556,589

- A) Indicated for anemia (Hgb < 10gm/dl or Hct < 30%) induced by cancer chemotherapy given within the previous 8 weeks or in the setting of myelodysplasia.
  - 1) Reassessment should be made after 8 weeks of treatment. If no response, treatment should be discontinued. If response is demonstrated, ESAs should be discontinued once the hemoglobin level reaches 10, unless a lower hemoglobin level is sufficient to avoid the need for red blood cell (RBC) transfusion.
- B) Indicated for anemia (Hgb < 10gm/dl or HCT < 30%) associated with HIV/AIDS.
  - 1) An endogenous erythropoietin level < 500 IU/L is required for treatment, and patient may not be receiving zidovudine (AZT) > 4200 mg/week.
  - 2) Reassessment should be made after 8 weeks. If no response, treatment should be discontinued. If response is demonstrated, the lowest ESA dose sufficient to reduce the need for RBC transfusions should be used, and the Hgb should not exceed 11gm/dl.
- C) Indicated for anemia (Hgb < 10 gm/dl or HCT <30%) associated with chronic renal failure, with or without dialysis.
  - 1) Reassessment should be made after 12 weeks. If no response, treatment should be discontinued. If response is demonstrated, the lowest ESA dose sufficient to reduce the need for RBC transfusions should be used, and the Hgb should not exceed 11gm/dl. In those not on dialysis, the Hgb level should not exceed 10gm/dl.

**GUIDELINE NOTE 8, BARIATRIC SURGERY**

Line 320

Bariatric/metabolic surgery (limited to Roux-en-Y gastric bypass, and sleeve gastrectomy) is included on Line 320 when the following criteria are met:

- A) Age ≥ 18
- B) The patient has obesity with a:
  - 1) BMI ≥ 40 OR
  - 2) BMI ≥ 35 with:
    - a) Type 2 diabetes, OR
    - b) at least two of the following other serious obesity-related comorbidities: hypertension, coronary heart disease, mechanical arthropathy in major weight bearing joint, sleep apnea
- C) Repeat bariatric surgery is included when it is a conversion from a less intensive (such as gastric band or sleeve gastrectomy) to a more intensive surgery (e.g. Roux-en-Y). Repair of surgical complications (excluding failure to lose sufficient weight) are also included on this and other lines. Reversal of surgical procedures and devices is included on this line when benefits of reversal outweigh harms.
- D) Participate in the following four evaluations and meet criteria as described.
  - 1) Psychosocial evaluation: (Conducted by a licensed mental health professional)
    - a) Evaluation to assess potential compliance with post-operative requirements.
    - b) Must remain free of abuse of or dependence on alcohol during the six-month period immediately preceding surgery. No current use of any nicotine product or illicit drugs and must remain abstinent from their use during the six-month observation period. Testing will, at a minimum, be conducted within 1 month of the quit date and within 1 month of the surgery to confirm abstinence from illicit drugs. Tobacco and nicotine abstinence to be confirmed in active users by negative cotinine levels at least 6 months apart, with the second test within one month of the surgery date.
    - c) No mental or behavioral disorder that may interfere with postoperative outcomes<sup>1</sup>.
    - d) Patient with psychiatric illness must be stable for at least 6 months.
  - 2) Medical evaluation: (Conducted by OHP primary care provider)
    - a) Pre-operative physical condition and mortality risk assessed with patient found to be an appropriate candidate.
    - b) Optimize medical control of diabetes, hypertension, or other co-morbid conditions.
    - c) Female patient not currently pregnant with no plans for pregnancy for at least 2 years post-surgery. Contraception methods reviewed with patient agreement to use effective contraception through 2nd year post-surgery.
  - 3) Surgical evaluation: (Conducted by a licensed bariatric surgeon associated with program<sup>2</sup>)
    - a) Patient found to be an appropriate candidate for surgery at initial evaluation and throughout period leading to surgery.
    - b) Received counseling by a credentialed expert on the team regarding the risks and benefits of the procedure and understands the many potential complications of the surgery (including death) and the realistic expectations of post-surgical outcomes.
  - 4) Dietician evaluation: (Conducted by licensed dietician)
    - a) Evaluation of adequacy of prior dietary efforts to lose weight. If no or inadequate prior dietary effort to lose weight, must undergo six-month clinically supervised weight reduction program (including intensive nutrition and physical activity counseling as defined by the USPSTF).
    - b) Counseling in dietary lifestyle changes
- E) Participate in additional evaluations:
  - 1) Post-surgical attention to lifestyle, an exercise program and dietary changes and understands the need for post-surgical follow-up with all applicable professionals (e.g. nutritionist, psychologist/psychiatrist, exercise physiologist or physical therapist, support group participation, regularly scheduled physician follow-up visits).

<sup>1</sup> Many patients (>50%) have depression as a co-morbid diagnosis that, if treated, would not preclude their participation in the bariatric surgery program.

**GUIDELINE NOTE 8, BARIATRIC SURGERY (CONT'D)**

<sup>2</sup> All surgical services must be provided by a program with current accreditation (as a comprehensive center or low acuity center) by the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP)

**GUIDELINE NOTE 9, WIRELESS CAPSULE ENDOSCOPY**

*Lines 29,56*

- A) Wireless capsule endoscopy is included on these lines for diagnosis of:
  - 1) Obscure GI bleeding suspected to be of small bowel origin with iron deficiency anemia or documented GI blood loss
  - 2) Suspected Crohn's disease with prior negative work up
- B) Wireless capsule endoscopy is not included on these lines for:
  - 1) Colorectal cancer screening
  - 2) Confirmation of lesions of pathology normally within the reach of upper or lower endoscopes (lesions proximal to the ligament of Treitz or distal to the ileum)
- C) Wireless capsule endoscopy is only included on these lines when the following conditions have been met:
  - 1) Prior studies must have been performed and been non-diagnostic
    - a) GI bleeding: upper and lower endoscopy
    - b) Suspected Crohn's disease: upper and lower endoscopy, small bowel follow through
  - 2) Radiological evidence of lack of stricture
  - 3) Only covered once during any episode of illness
  - 4) FDA approved devices must be used
  - 5) Patency capsule should not be used prior to procedure

**GUIDELINE NOTE 10, CENTRAL SEROUS CHORIORETINOPATHY AND POSTERIOR CYCLITIS**

*Lines 360,383*

Central serous chorioretinopathy (ICD-10-CM H35.71) is included on Line 383 only for treatment when the condition has been present for three months or longer. Posterior Cyclitis (ICD-10-CM H30.2) should only be treated in patients with 20/40 or worse vision.

**GUIDELINE NOTE 11, COLONY STIMULATING FACTOR (CSF) GUIDELINES**

*Lines 93,95,112-116,126,133,135,157,158,161,163,179,191,200,201,209,211,215,216,218,230,235,238,239,259-263,271,276,286-288,294,314-316,329,396,397,400,418,433,556,589*

- A) CSF are not indicated for primary prophylaxis of febrile neutropenia unless the primary chemotherapeutic regimen is known to produce febrile neutropenia at least 20% of the time. CSF should be considered when the primary chemotherapeutic regimen is known to produce febrile neutropenia 10-20% of the time; however, if the risk is due to the chemotherapy regimen, other alternatives such as the use of less myelosuppressive chemotherapy or dose reduction should be explored in this situation.
- B) For secondary prophylaxis, dose reduction should be considered the primary therapeutic option after an episode of severe or febrile neutropenia except in the setting of curable tumors (e.g., germ cell), as no disease free or overall survival benefits have been documented using dose maintenance and CSF.
- C) CSF are not indicated in patients who are acutely neutropenic but afebrile.
- D) CSF are not indicated in the treatment of febrile neutropenia except in patients who received prophylactic filgrastim or sargramostim or in high risk patients who did not receive prophylactic CSF. High risk patients include those age >65 years or with sepsis, severe neutropenia with absolute neutrophil count <100/mcl, neutropenia expected to be more than 10 days in duration, pneumonia, invasive fungal infection, other clinically documented infections, hospitalization at time of fever, or prior episode of febrile neutropenia.
- E) CSF are not indicated to increase chemotherapy dose-intensity or schedule, except in cases where improved outcome from such increased intensity has been documented in a clinical trial.
- F) CSF (other than pegfilgrastim) are indicated in the setting of autologous progenitor cell transplantation, to mobilize peripheral blood progenitor cells, and after their infusion.
- G) CSF are NOT indicated in patients receiving concomitant chemotherapy and radiation therapy.
- H) There is no evidence of clinical benefit in the routine, continuous use of CSF in myelodysplastic syndromes. CSF may be indicated for some patients with severe neutropenia and recurrent infections, but should be used only if significant response is documented.
- I) CSF is indicated for treatment of cyclic, congenital and idiopathic neutropenia.

**GUIDELINE NOTE 12, TREATMENT OF CANCER WITH LITTLE OR NO BENEFIT**

*Lines 93,112-116,125,129,133,135,157,158,163,179,191,200,201,209,211,215,216,218,230,235,238,239,259-263,271,276,286,287,294,314-316,329,372,396,397,418,433,589,600*

Cancer is a complex group of diseases with treatments that vary depending on the specific subtype of cancer and the patient's unique medical and social situation. Goals of appropriate cancer therapy can vary from intent to cure, disease burden reduction, disease stabilization and control of symptoms. Cancer care must always take place in the context of the patient's support systems, overall health, and core values. Patients should have access to appropriate peer-reviewed clinical trials of cancer therapies. A comprehensive multidisciplinary approach to treatment should be offered including palliative care services (see STATEMENT OF INTENT 1, PALLIATIVE CARE).

Treatment with intent to prolong survival is not a covered service for patients who have progressive metastatic cancer with

**GUIDELINE NOTE 12, TREATMENT OF CANCER WITH LITTLE OR NO BENEFIT (CONT'D)**

- A) Severe co-morbidities unrelated to the cancer that result in significant impairment in two or more major organ systems which would affect efficacy and/or toxicity of therapy; OR
- B) A continued decline in spite of best available therapy with a non reversible Karnofsky Performance Status or Palliative Performance score of <50% with ECOG performance status of 3 or higher which are not due to a pre-existing disability.

Treatments with intent to relieve symptoms or improve quality of life are covered as defined in STATEMENT OF INTENT 1, PALLIATIVE CARE.

Examples include:

- A) Single-dose radiation therapy for painful bone metastases with the intent to relieve pain and improve quality of life.
- B) Surgical decompression for malignant bowel obstruction.
- C) Medication therapy such as chemotherapy with low toxicity/low side effect agents with the goal to decrease pain from bulky disease or other identified complications. Cost of chemotherapy and alternative medication(s) should also be considered.

To qualify for treatment coverage, the cancer patient must have a documented discussion about treatment goals, treatment prognosis and the side effects, and knowledge of the realistic expectations of treatment efficacy. This discussion may take place with the patient's oncologist, primary care provider, or other health care provider, but preferably in a collaborative interdisciplinary care coordination discussion. Treatment must be provided via evidence-driven pathways (such as NCCN, ASCO, ASH, ASBMT, or NIH Guidelines) when available.

**GUIDELINE NOTE 13, HEMANGIOMAS, COMPLICATED**

*Lines 321,625*

Dermatologic hemangiomas (ICD-10-CM D18.01 Hemangioma and Lymphangioma of skin and subcutaneous tissue) are included on Line 321 when they are ulcerated, infected, recurrently hemorrhaging, or function-threatening (e.g. eyelid hemangioma). Otherwise, they are included on Line 625.

**GUIDELINE NOTE 14, SECOND BONE MARROW TRANSPLANTS**

*Lines 95,114,116,130,163,179,218,261,288*

Second bone marrow transplants are not covered except for tandem autologous transplants for multiple myeloma.

**GUIDELINE NOTE 15, HETEROTOPIC BONE FORMATION**

*Lines 81,356*

Radiation treatment is indicated only in those at high risk of heterotopic bone formation: those with a history of prior heterotopic bone formation, ankylosing spondylitis or hypertrophic osteoarthritis.

**GUIDELINE NOTE 16, PROTON BEAM THERAPY FOR CANCER**

*Lines 93,113,126,129,191,201,238,276,287,294,372,396,397*

Proton beam therapy is included on Lines 113 CANCER OF EYE AND ORBIT, 126 BENIGN NEOPLASM OF THE BRAIN AND SPINAL CORD and 294 CANCER OF BRAIN AND NERVOUS SYSTEM.

Proton beam therapy is included on Lines 129, 201 and 287 only for: malignant skull base, paranasal sinus (including lethal midline granuloma), spinal, and juxtaspinal tumors .

Proton beam therapy is additionally included on Lines 93, 191, 238, 276, 396 and 397 only for pediatric malignant tumors (incident cancer under age 21.)

**GUIDELINE NOTE 17, PREVENTIVE DENTAL CARE**

*Lines 3,53*

Dental cleaning is limited to once per 12 months for adults and twice per 12 months for children up to age 19 (D1110, D1120). More frequent dental cleanings may be required for certain higher risk populations.

Fluoride varnish (99188) is included on Line 3 for use with children 18 and younger during well child preventive care visits. Fluoride treatments (D1206 and D1208) are included on Line 53 PREVENTIVE DENTAL SERVICES for use with adults and children during dental visits. The total number of fluoride applications provided in all settings is not to exceed four per twelve months for a child at high risk for dental caries and two per twelve months for a child not at high risk. The number of fluoride treatments is limited to once per 12 months for average risk adults and up to four times per 12 months for high risk adults.

**GUIDELINE NOTE 18, VENTRICULAR ASSIST DEVICES**

*Lines 82,98,264*

Ventricular assist devices are covered as a bridge to cardiac transplant; as treatment for pulmonary hypertension when pulmonary hypertension is the only contraindication to cardiac transplant and the anticipated outcome is cardiac transplant; as a bridge to recovery; or as destination therapy.

When used as destination therapy, patients must

- A) have chronic end-stage heart failure (New York Heart Association Class IIIB or IV end-stage left ventricular failure) for more than 60 days, AND
- B) not be a candidate for heart transplantation, AND
- C) meet all of the following conditions:
  - 1) Have failed to respond to optimal medical management, including beta-blockers and ACE inhibitors (if tolerated) for at least 45 of the last 60 days, or have been balloon pump dependent for 7 days, or IV inotrope dependent for 14 days; and
  - 2) Have a left ventricular ejection fraction (LVEF) <25%; and
  - 3) Have demonstrated functional limitation with a peak oxygen consumption of <14 ml/kg/min unless balloon pump or inotrope dependent or physically unable to perform the test.
- D) Have adequate psychological condition and appropriate external psychosocial support for prolonged VAD support
- E) Have adequate end organ function

**GUIDELINE NOTE 19, PET SCAN GUIDELINES**

*Lines 113,116,133,135,157,158,163,174,200,201,211,230,260,263,276,287,314*

PET Scans are covered for diagnosis of the following cancers only:

- Solitary pulmonary nodules and non-small cell lung cancer
- Evaluation of cervical lymph node metastases when CT or MRI do not demonstrate an obvious primary tumor.

For diagnosis, PET is covered only when it will avoid an invasive diagnostic procedure, or will assist in determining the optimal anatomic location to perform an invasive diagnostic procedure.

PET scans are covered for the initial staging of the following cancers:

- Cervical cancer only when initial MRI or CT is negative for extra-pelvic metastasis
- Head and neck cancer when initial MRI or CT is equivocal
- Colon cancer
- Esophageal cancer
- Solitary pulmonary nodule
- Non-small cell lung cancer
- Lymphoma
- Melanoma

For staging, PET is covered when clinical management of the patient will differ depending on the stage of the cancer identified and either:

- A) the stage of the cancer remains in doubt after standard diagnostic work up, OR
- B) PET replaces one or more conventional imaging studies when they are insufficient for clinical management of the patient.

Restaging is covered only for cancers for which staging is covered and for thyroid cancer if recurrence is suspected and I131 scintigraphy is negative. For restaging, PET is covered after completion of treatment for the purpose of detecting residual disease, for detecting suspected recurrence or to determine the extent of a known recurrence. PET is not covered to monitor tumor response during the planned course of therapy. PET scans are NOT indicated for routine follow up of cancer treatment or routine surveillance in asymptomatic patients.

PET scans are also indicated for preoperative evaluation of the brain in patients who have intractable seizures and are candidates for focal surgery. PET scans are NOT indicated for cardiac evaluation.

**GUIDELINE NOTE 20, ATTENTION DEFICIT/HYPERACTIVITY DISORDERS IN CHILDREN**

*Line 122*

Use of ICD-10-CM F90.9, Attention deficit/hyperactivity disorder, unspecified type, in children age 5 and under, is appropriate only when the following apply:

- Child does not meet the full criteria for the full diagnosis because of their age.
- For children age 3 and under, when the child exhibits functional impairment due to hyperactivity that is clearly in excess of the normal activity range for age (confirmed by the evaluating clinician's observation, not only the parent/caregiver report), and when the child is very limited in his/her ability to have the sustained periods of calm, focused activity which would be expected for the child's age.

For children age 5 and under diagnosed with disruptive behavior disorders, including those at risk for ADHD, first line therapy is evidence-based, structured "parent-behavior training. Second line therapy is pharmacotherapy.

**GUIDELINE NOTE 20, ATTENTION DEFICIT/HYPERACTIVITY DISORDERS IN CHILDREN (CONT'D)**

For children age 6 and over who are diagnosed with ADHD, pharmacotherapy alone or pharmacotherapy with psychosocial/behavioral treatment are included on this line for first line therapy.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 21, SEVERE INFLAMMATORY SKIN DISEASE**

*Lines 424,480,502,530,539,654*

Inflammatory skin conditions included in this guideline are:

- A) Psoriasis
- B) Atopic dermatitis
- C) Lichen planus
- D) Darier disease
- E) Pityriasis rubra pilaris
- F) Discoid lupus

The conditions above are included on line 424 if severe, defined as having functional impairment (e.g. inability to use hands or feet for activities of daily living, or significant facial involvement preventing normal social interaction) AND one or more of the following:

- A) At least 10% of body surface area involved
- B) Hand, foot or mucous membrane involvement.

Otherwise, these conditions above are included on Lines 480, 502, 530, 539 and 654.

For severe psoriasis, first line agents include topical agents, phototherapy and methotrexate. Second line agents include other systemic agents and oral retinoids and should be limited to those who fail, or have contraindications to, or do not have access to first line agents. Biologics are included on this line only for the indication of severe plaque psoriasis; after documented failure of first line agents and failure of (or contraindications to) a second line agent.

For severe atopic dermatitis/eczema, first line agents include topical corticosteroids, narrowband UVB, cyclosporine, methotrexate, and azathioprine. Second line agents include topical pimecrolimus and topical tacrolimus and should be limited to those who fail or have contraindications to first line agents. Biologic agents are included on this line for atopic dermatitis only after failure of or contraindications to first and second line agents.

**GUIDELINE NOTE 22, PLANNED CESAREAN DELIVERY**

*Line 1*

Cesarean delivery on maternal request without medical or obstetrical indication is not included on this line (or the list). Planned cesarean delivery is also not included on this line (or the list) for: small for gestational age; suspected cephalopelvic disproportion; maternal Hepatitis B infection; or maternal Hepatitis C infection.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 23, COLON CANCER SURVEILLANCE**

*Line 157*

- A) History and physical exam is indicated every 3 to 6 months for the first three years after primary therapy, then annually thereafter.
- B) CEA testing should be performed every 2-3 months after colon resection for at least two years in patients with stage II or III disease for whom resection of liver metastases is clinically indicated
- C) Colonoscopy is indicated every 3 to 5 years.
- D) No other surveillance testing is indicated.

**GUIDELINE NOTE 24, COMPLICATED HERNIAS**

*Lines 168,522*

Complicated hernias are included on Line 168 if they cause symptoms of intestinal obstruction and/or strangulation. Incarcerated hernias (defined as non-reducible by physical manipulation) are also included on Line 168, excluding incarcerated ventral hernias. Incarcerated ventral hernias are included on Line 522, because the chronic incarceration of large ventral hernias does not place the patient at risk for impending strangulation.

**GUIDELINE NOTE 25, STEM CELL TRANSPLANTATION FOR NEUROBLASTOMA**

*Line 260*

Stem cell transplantation (CPT 38204-38215, 38230-38241) is only included on this line for treatment of high risk neuroblastoma (ICD-10-CM C74).

**GUIDELINE NOTE 26, BREAST CANCER SURVEILLANCE**

*Line 191*

- A) History and physical exam is indicated every 3 to 6 months for the first three years after primary therapy, then every 6-12 months for the next 2 years, then annually thereafter.
- B) Mammography is indicated annually, and patients treated with breast conserving therapy, initial mammogram of the affected breast should be 6 months after completion of radiotherapy.
- C) No other surveillance testing is indicated.

**GUIDELINE NOTE 27, SLEEP APNEA**

*Line 203*

CPAP is covered initially when all of the following conditions are met:

- 12 week 'trial' period to determine benefit. This period is covered if apnea-hypopnea index (AHI) or respiratory disturbance index (RDI) is greater than or equal to 15 events per hour; or if between 5 and 14 events with additional symptoms including one or more of the following:
  - excessive daytime sleepiness defined as either an Epworth Sleepiness Scale score >10 or daytime sleepiness interfering with ADLs that is not attributable to another modifiable sedating condition (e.g. narcotic dependence), or
  - documented hypertension, or
  - ischemic heart disease, or
  - history of stroke;
- Providers must provide education to patients and caregivers prior to use of CPAP machine to ensure proper use; and
- Positive diagnosis through polysomnogram (PSG) or Home Sleep Test (HST).

CPAP coverage subsequent to the initial 12 weeks is based on documented patient tolerance, compliance, and clinical benefit. Compliance (adherence to therapy) is defined as use of CPAP for at least four hours per night on 70% of the nights during a consecutive 30-day period.

Mandibular advancement devices (oral appliances) are covered for those for whom CPAP fails or is contraindicated.

Surgery for sleep apnea in adults is not included on this line (due to lack of evidence of efficacy). Surgical codes are included on this line only for children who meet criteria according to Guideline Note 118 OBSTRUCTIVE SLEEP APNEA DIAGNOSIS AND TREATMENT FOR CHILDREN.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 28, TROCHANTERIC BURSITIS**

*Lines 376,503*

Trochanteric bursitis (ICD-10-CM M70.6 and M70.7) is included on Line 376 for pairing with physical therapy and steroid joint injections. Trochanteric bursitis is included on Line 503 for pairing with surgical interventions (i.e. CPT 27062).

**GUIDELINE NOTE 29, TYMPANOSTOMY TUBES IN ACUTE OTITIS MEDIA**

*Line 389*

Tympanostomy tubes (CPT 69436) are only included on this line as treatment for:

- A) recurrent acute otitis media (three or more well-documented and separate episodes in six months or four or more well-documented and separate episodes in the past 12 months with at least one episode in the past six months) in patients who have unilateral or bilateral middle ear effusion at the time of assessment for tube candidacy, or
- B) patients with complicating conditions (immunocompromised host, meningitis by lumbar puncture, acute mastoiditis, sigmoid sinus/jugular vein thrombosis by CT/MRI/MRA, cranial nerve paralysis, sudden onset dizziness/vertigo, need for middle ear culture, labyrinthitis, or brain abscess).

Patients with craniofacial anomalies, Down's syndrome, cleft palate, permanent hearing loss of 25dB or greater independent of otitis media with effusion, and patients with speech and language delay may be considered for tympanostomy if unresponsive to appropriate medical treatment or having recurring infections (without needing to meet the strict "recurrent" definition above).

Removal of retained tympanostomy tubes requiring anesthesia (CPT code 69424) or as an office visit, is included on Line 422 as a complication, pairing with ICD-10-CM H74.8.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 30, TESTICULAR CANCER**

*Line 218*

The treatment of testicular cancer with bone marrow/stem cell rescue and transplant in conjunction with high-dose chemotherapy is included only after multiple (at least 2) recurrences after standard chemotherapy.

**GUIDELINE NOTE 31, COCHLEAR IMPLANTATION**

*Line 326*

Patients will be considered candidates for cochlear implants if the following criteria are met:

- A) Severe to profound sensorineural hearing loss in both ears (defined as 71dB hearing loss or greater at 500, 1000 and 2000 Hz)
- B) Receive limited useful benefit from appropriately fitted hearing aids, defined as a speech discrimination score of <30% on age appropriate testing for children and as scores of 40% or less on sentence recognition test in the best-aided listening condition for adults
- C) No medical contraindications
- D) High motivation and appropriate expectations (both patient and family, when appropriate)

Bilateral cochlear implants are included on this line. Simultaneous implantation appears to be more cost-effective than sequential implantation.

**GUIDELINE NOTE 32, CATARACT**

*Line 296*

Cataract extraction is covered for binocular visual acuity of 20/50 or worse OR monocular visual acuity of 20/50 or worse with the recent development of symptoms related to poor vision that affect activities of daily living (ADLs). Cataract removal must be likely to restore vision and allow the patient to resume activities of daily living. There are rare instances where cataract removal is medically necessary even if visual improvement is not the primary goal:

- A) Hypermature cataract causing inflammation and glaucoma OR
- B) To see the back of the eye to treat posterior segment conditions that could not be monitored due to the poor view and very dense lens opacity (i.e. diabetic retinopathy, glaucoma) OR
- C) Significant anisometropia causing aniseikonia.

**GUIDELINE NOTE 33, NITROUS OXIDE FOR LABOR PAIN**

*Line 1*

Nitrous oxide for labor pain is included on this line.

**GUIDELINE NOTE 34, EXTRACTION OF IMPACTED WISDOM TEETH**

*Line 344*

Extraction of impacted wisdom teeth (D7220, D7230, D7240, D7241, D7250) is only included on this line when there is

- A) Evidence of pathology. Such pathology includes unresorable caries, non-treatable pulpal and/or periapical pathology, cellulitis, abscess and osteomyelitis, internal/external resorption of the tooth or adjacent teeth, fracture of tooth, disease of follicle including cyst/tumour, tooth/teeth impeding surgery or reconstructive jaw surgery, and when a tooth is involved in or within the field of tumour resection OR
- B) Two or more episodes of pericoronitis OR
- C) Severe pain directly related to the impacted tooth that does not respond to conservative treatment. (Extraction for pain or discomfort related to normal tooth eruption or for non-specific symptoms such as "headaches" or "jaw pain" is not considered medically or dentally necessary for treatment.)

**GUIDELINE NOTE 35, SINUS SURGERY**

*Lines 287,463,504*

Sinus surgery (other than adenoidectomy) is indicated when at least one of the following circumstances occur (A-G):

- A) Recurrent acute rhinosinusitis, defined as 4 or more episodes of acute bacterial rhinosinusitis in one year without signs or symptoms of rhinosinusitis between episodes and have failed optimal medical management defined as nasal steroid therapy and nasal saline therapy, in patients who are compliant with oral antibiotics and/or oral corticosteroids for management of acute episodes of rhinosinusitis

OR

- B) Chronic sinusitis defined as 12 weeks of continuous symptoms without improvement with one of the following (1-3):
  - 1) Findings of obstruction of active infection on CT scan OR
  - 2) Symptomatic mucocele OR
  - 3) Negative CT scan but significant disease found on nasal endoscopy

AND

**GUIDELINE NOTE 35, SINUS SURGERY (CONT'D)**

Failure of medical therapy defined as (1-2)

4) Two or more courses of antibiotics with adequate doses AND

5) Trial of inhaled and/or oral steroids (2 or more courses of adequate doses of one or both)

OR

C) Nasal polyposis causing or contributing to sinusitis

OR

D) Complications of sinusitis including subperiosteal or orbital abscess, Pott's puffy tumor, brain abscess or meningitis

OR

E) Invasive or allergic fungal sinusitis

OR

F) Tumor of nasal cavity or sinuses

OR

G) CSF rhinorrhea

Adenoidectomy (CPT 42830, 42835) is included on Line 463 only for treatment of children with chronic sinusitis who fail appropriate medical therapy.

**GUIDELINE NOTE 36, ADENOTONSILLECTOMY FOR INDICATIONS OTHER THAN OBSTRUCTIVE SLEEP APNEA**

*Lines 42,47,368,548*

Tonsillectomy/adentonsillectomy is an appropriate treatment for patients with:

- A) Five documented attacks of strep tonsillitis in a year or 3 documented attacks of strep tonsillitis in each of two consecutive years where an attack is considered a positive culture/screen and where an appropriate course of antibiotic therapy has been completed;
- B) Peritonsillar abscess requiring surgical drainage; or,
- C) Unilateral tonsillar hypertrophy in adults; unilateral tonsillar hypertrophy in children with other symptoms suggestive of malignancy.

ICD-10-CM J35.1 and J35.3 are included on Line 368 only for 1) unilateral tonsillar hypertrophy in adults and 2) unilateral tonsillar hypertrophy in children with other symptoms suggestive of malignancy. Bilateral tonsillar hypertrophy and unilateral tonsillar hypertrophy in children without other symptoms suggestive of malignancy are included only on Line 548.

See Guideline Note 118 for diagnosis and treatment of obstructive sleep apnea in children.

**GUIDELINE NOTE 37, SURGICAL INTERVENTIONS FOR CONDITIONS OF THE BACK AND SPINE OTHER THAN SCOLIOSIS**

*Lines 346,527*

Spine surgery is included on Line 346 only in the following circumstances:

- A) Decompressive surgery is included on Line 346 to treat debilitating symptoms due to central or foraminal spinal stenosis, and only when the patient meets the following criteria:
  - 1) Has MRI evidence of moderate or severe central or foraminal spinal stenosis AND
  - 2) Has neurogenic claudication OR
  - 3) Has objective neurologic impairment consistent with the MRI findings. Neurologic impairment is defined as objective evidence of one or more of the following:
    - a) Markedly abnormal reflexes
    - b) Segmental muscle weakness
    - c) Segmental sensory loss
    - d) EMG or NCV evidence of nerve root impingement
    - e) Cauda equina syndrome
    - f) Neurogenic bowel or bladder
    - g) Long tract abnormalitiesForaminal or central spinal stenosis causing only radiating pain (e.g. radiculopathic pain) is included only on Line 527.
- B) Spinal fusion procedures are included on Line 346 for patients with MRI evidence of moderate or severe central spinal stenosis only when one of the following conditions are met:
  - 1) spinal stenosis in the cervical spine (with or without spondylolisthesis) which results in objective neurologic impairment as defined above OR
  - 2) spinal stenosis in the thoracic or lumbar spine caused by spondylolisthesis resulting in signs and symptoms of neurogenic claudication and which correlate with xray flexion/extension films showing at least a 5 mm translation OR
  - 3) pre-existing or expected post-surgical spinal instability (e.g. degenerative scoliosis >10 deg, >50% of facet joints per level expected to be resected)

For all other indications, spine surgery is included on Line 527.

The following interventions are not included on these lines due to lack of evidence of effectiveness for the treatment of conditions on these lines, including cervical, thoracic, lumbar, and sacral conditions:

- prolotherapy
- local injections
- botulinum toxin injection

**GUIDELINE NOTE 37, SURGICAL INTERVENTIONS FOR CONDITIONS OF THE BACK AND SPINE OTHER THAN SCOLIOSIS (CONT'D)**

- intradiscal electrothermal therapy
- therapeutic medial branch block
- coblation nucleoplasty
- percutaneous intradiscal radiofrequency thermocoagulation
- radiofrequency denervation
- corticosteroid injections for cervical pain

Corticosteroid injections for low back pain with or without radiculopathy are only included on Line 527.

The development of this guideline note was informed by HERC coverage guidances on [Percutaneous Interventions for Low Back Pain](#), [Percutaneous Interventions for Cervical Spine Pain](#) and [Low Back Pain: Corticosteroid Injections](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 38, SUBTALAR ARTHROEREISIS**

*Line 377*

Procedure code S2117 is only covered when not incorporating an implant device.

**GUIDELINE NOTE 39, ENDOMETRIOSIS AND ADENOMYOSIS**

*Lines 1,395*

- A) Hysterectomy, with or without adnexectomy, for endometriosis may be appropriate when all of the following are documented (1-4):
- 1) Patient history of (a and b):
    - a) Prior detailed operative description or histologic diagnosis of endometriosis
    - b) Presence of pain for more than 6 months with negative effect on patient's quality of life
  - 2) Failure of a 3-month therapeutic trial with both of the following (a and b), unless there are contraindications to use:
    - a) Hormonal therapy (i or ii):
      - i) Oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar
      - ii) Agents for inducing amenorrhea (e.g., GnRH analogs or danazol)
    - b) Nonsteroidal anti-inflammatory drugs
  - 3) Nonmalignant cervical cytology, if cervix is present
  - 4) Negative preoperative pregnancy test result unless patient is postmenopausal or has been previously sterilized
- B) Hysterectomy, with or without adnexectomy, for adenomyosis may be appropriate when all of the following are documented (1-5):
- 1) Patient history of dysmenorrhea, pelvic pain or abnormal uterine bleeding for more than six months with a negative effect on her quality of life.
  - 2) Failure of a six-month therapeutic trial with both of the following (a and b), unless there are contraindications to use:
    - a) Hormonal therapy (i or ii):
      - i) Oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar
      - ii) Agents for inducing amenorrhea (e.g., GnRH analogs or danazol)
    - b) Nonsteroidal anti-inflammatory drugs
  - 3) One of the following (a or b):
    - a) Endovaginal ultrasound suspicious for adenomyosis (presence of abnormal hypoechoic myometrial echogenicity or presence of small myometrial cysts)
    - b) MRI showing thickening of the junctional zone > 12mm
  - 4) Nonmalignant cervical cytology, if cervix is present
  - 5) Negative preoperative pregnancy test unless patient is postmenopausal or has been previously sterilized

**GUIDELINE NOTE 40, UTERINE LEIOMYOMA**

*Line 403*

Hysterectomy, myomectomy, or uterine artery embolization for leiomyomata may be indicated when all of the following are documented (A-D):

- A) One of the following (1 or 2):
- 1) Patient history of 2 out of 3 of the following (a, b and c):
    - a. Leiomyomata enlarging the uterus to a size of 12 weeks or greater gestation
    - b. Pelvic discomfort caused by myomata (i or ii or iii):
      - i) Chronic lower abdominal, pelvic or low back pressure
      - ii) Bladder dysfunction not due to urinary tract disorder or disease
      - iii) Rectal pressure and bowel dysfunction not related to bowel disorder or disease
    - c. Rapid enlargement causing concern for sarcomatous changes of malignancy
  - 2) Leiomyomata as probable cause of excessive uterine bleeding evidenced by (a, b, c and d):
    - a. Profuse bleeding lasting more than 7 days or repetitive periods at less than 21-day intervals
    - b. Anemia due to acute or chronic blood loss (hemoglobin less than 10 or hemoglobin less than 11 g/dL if use of iron is documented)

**GUIDELINE NOTE 40, UTERINE LEIOMYOMA (CONT'D)**

- c. Documentation of mass by sonography
- d. Bleeding causes major impairment or interferes with quality of life
- B) Nonmalignant cervical cytology, if cervix is present
- C) Assessment for absence of endometrial malignancy in the presence of abnormal bleeding
- D) Negative preoperative pregnancy test result unless patient is postmenopausal or has been previously sterilized

**GUIDELINE NOTE 41, SCOLIOSIS**

*Line 361*

Non-surgical treatments of scoliosis (ICD-10-CM M41) are included on Line 361 when

- 1) the scoliosis is considered clinically significant, defined as curvature greater than or equal to 25 degrees, or
- 2) there is curvature with a documented rapid progression.

Surgical treatments of scoliosis are included on Line 361

- 1) only for children and adolescents (age 20 and younger) with
- 2) a spinal curvature of greater than 45 degrees

**GUIDELINE NOTE 42, CHEMODENERVATION FOR CHRONIC MIGRAINE**

*Line 409*

Chemodenervation for treatment of chronic migraine (CPT 64615) is included on this line for prophylactic treatment of adults who meet all of the following criteria:

- A) have chronic migraine defined as headaches on at least 15 days per month of which at least 8 days are with migraine
- B) has not responded to or have contraindications to at least three prior pharmacological prophylaxis therapies (beta-blocker, calcium channel blocker, anticonvulsant or tricyclic antidepressant)
- C) treatment is administered in consultation with a neurologist or headache specialist.

Treatment is limited to two injections given 3 months apart. Additional treatment requires documented positive response to therapy. Positive response to therapy is defined as a reduction of at least 7 headache days per month compared to baseline headache frequency.

**GUIDELINE NOTE 43, LYMPHEDEMA**

*Line 421*

Lymphedema treatments are included on this line when medically appropriate. These services are to be provided by a licensed practitioner who is certified by one of the accepted lymphedema training certifying organizations or a graduate of one of the National Lymphedema Network accepted training courses within the past two years. The only accepted certifying organization at this time is LANA (Lymphology Association of North America; <http://www.clt-lana.org>). Treatments for lymphedema are not subject to the visit number restrictions found in Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES.

It is the intent of the HERC that compression dressings/garments and other medical equipment needed for the treatment of lymphedema be covered even in the absence of ulcers or other complications.

**GUIDELINE NOTE 44, MENSTRUAL BLEEDING DISORDERS**

*Line 420*

Endometrial ablation or hysterectomy for abnormal uterine bleeding in Premenopausal women may be indicated when all of the following are documented (A-C):

- A) Patient history of (1, 2, 3, 4, and 5):
  - 1) Excessive uterine bleeding evidence by (a, b and c):
    - a) Profuse bleeding lasting more than 7 days or repetitive periods at less than 21-day intervals
    - b) Anemia due to acute or chronic blood loss (hemoglobin less than 10 g/dL or hemoglobin less than 11 g/dL if use of iron is documented)
    - c) Bleeding causes major impairment or interferes with quality of life
  - 2) Failure of hormonal treatment for a six-month trial period or contraindication to hormone use (oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar)
  - 3) No current medication use that may cause bleeding, or contraindication to stopping those medications
  - 4) Endometrial sampling performed
  - 5) No evidence of treatable intrauterine conditions or lesions by (a, b or c):
    - a) Sonohysterography
    - b) Hysteroscopy
    - c) Hysterosalpingography
- B) Negative preoperative pregnancy test result unless patient has been previously sterilized
- C) Nonmalignant cervical cytology, if cervix is present

**GUIDELINE NOTE 45, CHEMODENERVATION OF THE BLADDER**

*Line 327*

Chemodenervation of the bladder (CPT 52287) is included on this line only for treatment of idiopathic detrusor over-activity or neurogenic detrusor over-activity (ICD-10-CM N32.81) in patients who have not responded to or been unable to tolerate at least two urinary incontinence antimuscarinic therapies (e.g. fesoterodine, oxybutynin, solifenacin, darifenacin, tolterodine, trospium). Treatment is limited to 90 days, with additional treatment only if the patient shows documented positive response. Positive response to therapy is defined as a reduction of urinary frequency of 8 episodes per day or urinary incontinence of 2 episodes per day compared to baseline frequency.

**GUIDELINE NOTE 46, AGE-RELATED MACULAR DEGENERATION**

*Line 447*

Pegaptanib is only covered for minimally classic and occult lesions of wet macular degeneration.

**GUIDELINE NOTE 47, URINARY INCONTINENCE**

*Line 453*

Surgery for genuine stress urinary incontinence may be indicated when all of the following are documented (A-G):

- A) Patient history of (1, 2, and 3):
  - 1) Involuntary loss of urine with exertion
  - 2) Identification and treatment of transient causes of urinary incontinence, if present (e.g., delirium, infection, pharmaceutical causes, psychological causes, excessive urine production, restricted mobility, and stool impaction)
  - 3) Involuntary loss of urine on examination during stress (provocative test with direct visualization of urine loss) and low or absent post void residual
- B) Patient's voiding habits
- C) Physical or laboratory examination evidence of either (1 or 2):
  - 1) Urethral hypermobility
  - 2) Intrinsic sphincter deficiency
- D) Diagnostic workup to rule out urgency incontinence
- E) Negative preoperative pregnancy test result unless patient is postmenopausal or has been previously sterilized
- F) Nonmalignant cervical cytology, if cervix is present
- G) Patient required to have 3 months of alternative therapy (e.g., pessaries or physical therapy, including bladder training, pelvic floor exercises and/or biofeedback, as available). If limited coverage of physical therapy is available, patients should be taught pelvic floor exercises by their treating provider, physical therapist or trained staff, and have documented consistent practice of these techniques over the 3 month period.

**GUIDELINE NOTE 48, FRENULECTOMY/FRENULOTOMY**

*Line 344*

Frenulectomy/frenulotomy (D7960) is included on this line for the following situations:

- A) When deemed to cause gingival recession
- B) When deemed to cause movement of the gingival margin when frenum is placed under tension.
- C) Maxillary labial frenulectomy not covered until age 12 and above.

**GUIDELINE NOTE 49, WEARABLE CARDIAC DEFIBRILLATORS**

*Lines 69,99,111,189,281,347*

Wearable cardiac defibrillators (WCDs; CPT 93745, HCPCS K0606-K0609) are included on these lines for patients at high risk for sudden cardiac death who meet the medical necessity criteria for an implantable cardioverter defibrillator (ICD) as defined by the CMS 2005 National Coverage Determination but are unable to have an ICD implanted due to medical condition (e.g. ICD explanted due to infection with waiting period before ICD reinsertion or current medical condition contraindicates surgery). WCDs are not included on these lines for use during the waiting period for ICD implantation after myocardial infarction, coronary bypass surgery, or coronary artery stenting.

**GUIDELINE NOTE 50, PELVIC ORGAN PROLAPSE SURGERY**

*Line 464*

Hysterectomy, cystocele repair, and/or other surgery for pelvic organ prolapse may be indicated when all of the following are documented (A-E):

- A) Patient history of symptoms of pelvic prolapse such as:
  - 1) Complaints of the pelvic organs prolapsing at least to the introitus, and one or more of the following:
    - a) Low back discomfort or pelvic pressure, or
    - b) Difficulty in defecating, or
    - c) Difficulty in voiding
- B) For hysterectomy
  - 1) Nonmalignant cervical cytology, if cervix is present, and

**GUIDELINE NOTE 50, PELVIC ORGAN PROLAPSE SURGERY (CONT'D)**

- 2) Assessment for absence of endometrial malignancy in the presence of abnormal bleeding
- C) Physical examination is consistent with patient's symptoms of pelvic support defects indicating either symptomatic prolapse of the cervix, enterocele, cystocele, rectocele or prolapse of the vaginal vault
- D) Negative preoperative pregnancy test unless patient is postmenopausal or has been previously sterilized
- E) Patient required to have 3 months of alternative therapy (e.g., pessaries or physical therapy, including bladder training, pelvic floor exercises and/or biofeedback, as available). If limited coverage of physical therapy is available, patients should be taught pelvic floor exercises by their treating provider, physical therapist or trained staff, and have documented consistent practice of these techniques over the 3 month period.

**GUIDELINE NOTE 51, CHRONIC OTITIS MEDIA WITH EFFUSION**

*Lines 311,444,473*

Antibiotic and other medication therapy (including antihistamines, decongestants, and nasal steroids) are not indicated for children with chronic otitis media with effusion (OME) (without another appropriate diagnosis).

Patients with specific higher risk conditions (including craniofacial anomalies, Down's syndrome, and cleft palate, or documented speech and language delay) along with hearing loss and chronic otitis media with effusion are intended to be included on Line 311 or Line 444 for children up to and including age 7. Otherwise hearing loss associated with chronic otitis media with effusion (without those specific higher risk conditions) is only included on Line 473.

For coverage to be considered on Line 311, Line 444 or Line 473, there should be a 3 to 6 month watchful waiting period after diagnosis of otitis media with effusion, and if documented hearing loss is greater than or equal to 25dB in the better hearing ear, tympanostomy surgery may be indicated, given short- but not long- term improvement in hearing. Formal audiometry is indicated for children with chronic OME present for 3 months or longer. Children with language delay, learning problems, or significant hearing loss should have hearing testing upon diagnosis. Children with chronic OME who are not at risk for language delay (such as those with hearing loss <25dB in the better hearing ear) or developmental delay should be reexamined at 3- to 6-month intervals until the effusion is no longer present, significant hearing loss is identified, or structural abnormalities of the eardrum or middle ear are suspected.

Adenoidectomy is not indicated at the time of first pressure equalization tube insertion. It may be indicated in children aged 4 and older who are having their second set of tubes.

Removal of retained tympanostomy tubes requiring anesthesia (CPT code 69424) or as an office visit, is included on Line 422 as a complication, pairing with ICD-10-CM H74.8.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 52, CHRONIC ANAL FISSURE**

*Line 524*

Surgery for chronic anal fissure (ICD-10-CM K60.1) is included in this line with one or more of the following:

- A) Condition unresponsive to six to eight weeks of continuous treatment;
- B) Condition progresses in spite of six to eight weeks of treatment;
- C) Presence of pectenosis; and/or,
- D) Fissures that have previously healed but have recurred three or more times.

**GUIDELINE NOTE 53, BASIC PERIODONTICS**

*Line 219*

Only for the treatment of severe drug-induced hyperplasia (D4210, D4211, D4212). Payable only when there are pockets of 5 mm or greater (D4341).

**GUIDELINE NOTE 54, CONDUCT DISORDER**

*Line 477*

Conduct disorder rarely occurs in isolation from other psychiatric diagnosis, the patient should have documented screening for attention deficit/hyperactivity disorder (ADHD); chemical dependency (CD); mood disorders such as anxiety and/or depression; and physical, sexual, and family abuse or other trauma (PTSD).

**GUIDELINE NOTE 55, PELVIC PAIN SYNDROME**

*Line 529*

- A) Diagnostic MRI may be indicated for evaluation of pelvic pain to assess for Adenomyosis and to assist in the management of these challenging patients when all of the following are documented:
  - 1) Patient history of dysmenorrhea, pelvic pain or abnormal uterine bleeding for more than six months with a negative effect on her quality of life.
  - 2) Failure of a six-month therapeutic trial with both of the following (a and b), unless there are contraindications to use:

**GUIDELINE NOTE 55, PELVIC PAIN SYNDROME (CONT'D)**

- a) Hormonal therapy (i or ii):
    - i) Oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar
    - ii) Agents for inducing amenorrhea (e.g., GnRH analogs or danazol)
  - b) Nonsteroidal anti-inflammatory drugs
  - 3) An endovaginal ultrasound within the past 12 months that shows no other suspected gynecological pathology if diagnostic MRI shows > 12mm thickening of the junctional zone, the presumptive diagnosis of adenomyosis is fulfilled. See Guideline Note 39.
- B) Hysterectomy for chronic pelvic pain in the absence of significant pathology may be Indicated when all of the following are documented (1-7):
- 1) Patient history of:
    - a) No treatable conditions or lesions found on laparoscopic examination
    - b) Pain for more than 6 months with negative effect on patient's quality of life
  - 2) Failure of a six-month therapeutic trial with both of the following (a and b), unless there are contraindications to use:
    - a) Hormonal therapy (i or ii):
      - i) Oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar
      - ii) Agents for inducing amenorrhea (e.g., GnRH analogs or danazol)
    - b) Nonsteroidal anti-inflammatory drugs
  - 3) Evaluation of the following systems as possible sources of pelvic pain:
    - a) Urinary
    - b) Gastrointestinal
    - c) Musculoskeletal
  - 4) Evaluation of the patient's psychologic and psychosexual status for nonsomatic cause of symptoms
  - 5) Nonmalignant cervical cytology, if cervix is present
  - 6) Assessment for absence of endometrial malignancy in the presence of abnormal bleeding
  - 7) Negative preoperative pregnancy test unless patient is postmenopausal or as been previously sterilized

**GUIDELINE NOTE 56, NON-INTERVENTIONAL TREATMENTS FOR CONDITIONS OF THE BACK AND SPINE**

*Lines 361,401*

Patients seeking care for back pain should be assessed for potentially serious conditions ("red flag" symptoms requiring immediate diagnostic testing), as defined in Diagnostic Guideline D4. Patients lacking red flag symptoms should be assessed using a validated assessment tool (e.g. STarT Back Assessment Tool) in order to determine their risk level for poor functional prognosis based on psychosocial indicators.

For patients who are determined to be low risk on the assessment tool, the following services are included on these lines:

- Office evaluation and education,
- Up to four total visits, consisting of the following treatments: OMT/CMT, acupuncture, and PT/OT. Massage, if available, may be provided as part of these four total visits.
- First line medications: NSAIDs, acetaminophen, and/or muscle relaxers. Opioids may be considered as a second line treatment, subject to the limitations on coverage of opioids in Guideline Note 60 OPIOIDS FOR CONDITIONS OF THE BACK AND SPINE. See evidence table.

For patients who are determined to be medium- or high risk on the validated assessment tool, as well as patients undergoing opioid tapers as in Guideline Note 60 OPIOIDS FOR CONDITIONS OF THE BACK AND SPINE, the following treatments are included on these lines:

- Office evaluation, consultation and education
- Cognitive behavioral therapy. The necessity for cognitive behavioral therapy should be re-evaluated every 90 days and coverage will only be continued if there is documented evidence of decreasing depression or anxiety symptomatology, improved ability to work/function, increased self-efficacy, or other clinically significant, objective improvement.
- Prescription and over-the-counter medications; opioid medications subject to the limitations on coverage of opioids in Guideline Note 60 OPIOIDS FOR CONDITIONS OF THE BACK AND SPINE. See evidence table.
- The following evidence-based therapies, when available, may be provided: yoga, massage, supervised exercise therapy, intensive interdisciplinary rehabilitation. HCPCS S9451 is only included on Line 401 for the provision of yoga or supervised exercise therapy.
- A total of 30 visits per year of any combination of the following evidence-based therapies when available and medically appropriate. These therapies are only included on these lines if provided by a provider licensed to provide the therapy and when there is documentation of measurable clinically significant progress toward the therapy plan of care goals and objectives using evidence based objective tools (e.g. Oswestry, Neck Disability Index, SF-MPQ, and MSPQ).
  - 1) Rehabilitative therapy (physical and/or occupational therapy), if provided according to Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES. Rehabilitation services provided under this guideline also count towards visit totals in Guideline Note 6. CPT 97124 is included in this category.
  - 2) Chiropractic or osteopathic manipulation
  - 3) Acupuncture

Mechanical traction (CPT 97012) is not included on these lines, due to evidence of lack of effectiveness for treatment of back and neck conditions.

The development of this guideline note was informed by HERC coverage guidances on [Low Back Pain Non-Pharmacologic, Non-Invasive Intervention, Low Back Pain, Pharmacological and Herbal Therapies](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 56, NON-INTERVENTIONAL TREATMENTS FOR CONDITIONS OF THE BACK AND SPINE (CONT'D)****Evidence Table of Effective Treatments for the Management of Low Back Pain**

Intervention Category*	Intervention	Acute < 4 Weeks	Subacute & Chronic > 4 Weeks
Self-care	Advice to remain active	●	●
	Books, handout	●	●
	Application of superficial heat	●	
Nonpharmacologic therapy	Spinal manipulation	●	●
	Exercise therapy		●
	Massage		●
	Acupuncture		●
	Yoga		●
	Cognitive-behavioral therapy		●
	Progressive relaxation		●
Pharmacologic therapy (Carefully consider risks/harms)	Acetaminophen	●	●
	NSAIDs	●(▲)	●(▲)
	Skeletal muscle relaxants	●	
	Antidepressants (TCA)		●
	Benzodiazepines**	●(▲)	●(▲)
	Tramadol, opioids**	●(▲)	●(▲)
Interdisciplinary therapy	Intensive interdisciplinary rehabilitation		●
<p>● Interventions supported by grade B evidence (at least fair-quality evidence of moderate benefit, or small benefit but no significant harms, costs, or burdens). No intervention was supported by grade "A" evidence (good-quality evidence of substantial benefit).</p> <p>▲ Carries greater risk of harms than other agents in table.</p>			

NSAIDs = nonsteroidal anti-inflammatory drugs; TCA = tricyclic antidepressants.

\*These are general categories only. Individual care plans need to be developed on a case by case basis. For more detailed information please see: <http://www.annals.org/content/147/7/478.full.pdf>

\*\*Associated with significant risks related to potential for abuse, addiction and tolerance. This evidence evaluates effectiveness of these agents with relatively short term use studies. Chronic use of these agents may result in significant harms.

**GUIDELINE NOTE 57, PELVIC PHYSICAL THERAPY FOR INTERSTITIAL CYSTITIS**

Line 327

Pelvic physical therapy (CPT 97140 and 97161-97164) is included on this line only for treatment of interstitial cystitis in patients who present with pelvic floor tenderness. Such pelvic PT is only included on this line when provided by professionals trained and experienced in pelvic floor therapy and as limited in Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES.

**GUIDELINE NOTE 58, IMPULSE DISORDERS**

Line 544

Impulse disorders rarely occur in isolation from other psychiatric diagnosis, thus the Patient should have documented screening for attention deficit/hyperactivity disorder (ADHD); chemical dependency (CD); mood disorders such as anxiety and/or depression; and physical, sexual, and family abuse or other trauma (PTSD).

**GUIDELINE NOTE 59, DYSMENORRHEA**

Line 555

Hysterectomy for dysmenorrhea may be indicated when all of the following are documented (A-G):

- A) Patient history of:
- 1) No treatable conditions or lesions found on laparoscopic examination
  - 2) Pain for more than 6 months with negative effect on patient's quality of life

**GUIDELINE NOTE 59, DYSMENORRHEA (CONT'D)**

- B) Failure of a six-month therapeutic trial with both of the following (1 and 2), unless there are contraindications to use:
  - 1) Hormonal therapy (a or b):
    - a) Oral contraceptive pills or patches, progesterone-containing IUDs, injectable hormone therapy, or similar
    - b) Agents for inducing amenorrhea (e.g., GnRH analogs or danazol)
  - 2) Nonsteroidal anti-inflammatory drugs
- C) Evaluation of the following systems as possible sources of pelvic pain:
  - 1) Urinary
  - 2) Gastrointestinal
  - 3) Musculoskeletal
- D) Evaluation of the patient's psychologic and psychosexual status for nonsomatic cause of symptoms
- E) Nonmalignant cervical cytology, if cervix is present
- F) Assessment for absence of endometrial malignancy in the presence of abnormal bleeding
- G) Negative preoperative pregnancy test unless patient is postmenopausal or has been previously sterilized

**GUIDELINE NOTE 60, OPIOIDS FOR CONDITIONS OF THE BACK AND SPINE**

*Lines 346,361,401,527*

Opioid medications are only included on these lines under the following criteria:

For acute injury, acute flare of chronic pain, or after surgery:

- 1) During the first 6 weeks opioid treatment is included on these lines ONLY:
  - a) When each prescription is limited to 7 days of treatment, AND
  - b) For short acting opioids only, AND
  - c) When one or more alternative first line pharmacologic therapies such as NSAIDs, acetaminophen, and muscle relaxers have been tried and found not effective or are contraindicated, AND
  - d) When prescribed with a plan to keep active (home or prescribed exercise regime) and with consideration of additional therapies such as spinal manipulation, physical therapy, yoga, or acupuncture, AND
  - e) There is documented verification that the patient is not high risk for opioid misuse or abuse.
- 2) Treatment with opioids after 6 weeks, up to 90 days after the initial injury/flare/surgery is included on these lines ONLY:
  - a) With documented evidence of improvement of function of at least thirty percent as compared to baseline based on a validated tools (e.g. Oswestry, Neck Disability Index, SF-MPQ, and MSPQ).
  - b) When prescribed in conjunction with therapies such as spinal manipulation, physical therapy, yoga, or acupuncture.
  - c) With verification that the patient is not high risk for opioid misuse or abuse. Such verification may involve
    - i) Documented verification from the state's prescription monitoring program database that the controlled substance history is consistent with the prescribing record
    - ii) Use of a validated screening instrument to verify the absence of a current substance use disorder (excluding nicotine) or a history of prior opioid misuse or abuse
    - iii) Administration of a baseline urine drug test to verify the absence of illicit drugs and non-prescribed opioids.
  - d) Each prescription must be limited to 7 days of treatment and for short acting opioids only
- 3) Chronic opioid treatment (>90 days) after the initial injury/flare/surgery is not included on these lines except for the taper process described below.

Transitional coverage for patients on long-term opioid therapy as of July 1, 2016:

For patients on covered chronic opioid therapy as of July 1, 2016, opioid medication is included on these lines only from July 1, 2016 to December 31, 2016. During the period from January 1, 2017 to December 31, 2017, continued coverage of opioid medications requires an individual treatment plan developed by January 1, 2017 which includes a taper with an end to opioid therapy no later than January 1, 2018. Taper plans must include nonpharmacological treatment strategies for managing the patient's pain based on Guideline Note 56 NON-INTERVENTIONAL TREATMENTS FOR CONDITIONS OF THE BACK AND SPINE. If a patient has developed dependence and/or addiction related to their opioids, treatment is available on Line 4 SUBSTANCE USE DISORDER.

**GUIDELINE NOTE 61, HOSPITALIZATION FOR ACUTE VIRAL INFECTIONS**

*Lines 140,533,546,550,612*

Most acute viral infections are self-limited (e.g. colds, infectious mononucleosis, gastroenteritis). However, some viral infections such as aseptic meningitis, or severe gastroenteritis may require hospitalization to treat the complications of the primary disease.

Accepted coding practices insist that the underlying condition in these cases be the principle diagnosis. For example, complicated viral pneumonia requiring respiratory support with a ventilator would have a principle diagnosis of viral pneumonia and a secondary diagnosis of respiratory failure. Since the diagnosis code for viral pneumonia has historically appeared only on a non-funded line, treatment has not been reimbursable regardless of the severity of the disease. In contrast, the code for viral gastroenteritis appears on Line 146 and any necessary outpatient or inpatient services would be covered.

Reimbursement for the treatment of certain conditions appearing low on the Prioritized List should be provided in severe cases of the diseases identified on the following four lines.

Line: 550

**GUIDELINE NOTE 61, HOSPITALIZATION FOR ACUTE VIRAL INFECTIONS (CONT'D)**

Condition: OTHER NONINFECTIOUS GASTROENTERITIS AND COLITIS  
Treatment: MEDICAL THERAPY

Treatment of non-infectious gastroenteritis of significant severity that is associated with dehydration should be a covered service if the case fulfills the requirement of hospital admission guidelines using an index of severity of illness.

Line: 533  
Condition: VIRAL, SELF-LIMITING ENCEPHALITIS, MYELITIS AND ENCEPHALOMYELITIS  
Treatment: MEDICAL THERAPY

Treatment of viral encephalitis, myelitis and encephalomyelitis of significant severity that is associated with either obtundation or dehydration should be a covered service if the case fulfills the requirement of hospital admission guidelines using an index of severity of illness.

Line: 546  
Condition: ASEPTIC MENINGITIS  
Treatment: MEDICAL THERAPY

Treatment of aseptic meningitis of significant severity that is associated with either obtundation or dehydration should be a covered service if the case fulfills the requirement of hospital admission guidelines using an index of severity of illness.

Line: 611  
Condition: ACUTE UPPER RESPIRATORY INFECTIONS AND COMMON COLD  
Treatment: MEDICAL THERAPY

Line: 612  
Condition: OTHER VIRAL INFECTIONS  
Treatment: MEDICAL THERAPY

Line: 649  
Condition: INFECTIOUS DISEASES WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY  
Treatment: EVALUATION

Treatment of acute infectious disease that is associated with respiratory failure, obtundation/altered mental status, or dehydration should be a covered service if the case fulfills the requirement of hospital admission guidelines using an index of severity of illness.

**GUIDELINE NOTE 62, NEGATIVE PRESSURE WOUND THERAPY**

*Lines 8,27,47,80,206,208,236,285,379,422*

Negative pressure wound therapy (CPT 97605-97608) is included on these lines only for patients who:

- Have wounds that are refractory to or have failed standard therapies;
- Are not suitable candidates for surgical wound closure; or,
- Are at high risk for delayed or non-healing wounds due to factors such as compromised blood flow, diabetic complications, wounds with high risk of fecal contamination, extremely exudative wounds, and similar situations.

**GUIDELINE NOTE 63, HYDROCELE REPAIR**

*Line 168*

Excision of hydrocele is only covered for children age 18 and younger with hydroceles which persist after 18 months of age.

**GUIDELINE NOTE 64, PHARMACIST MEDICATION MANAGEMENT**

*Included on all lines with evaluation & management (E&M) codes*

Pharmacy medication management services must be provided by a pharmacist who has:

- 1) A current and unrestricted license to practice as a pharmacist in Oregon.
- 2) Documentation must be provided for each consultation and must reflect communication with the patient's primary care provider. Documentation should model SOAP charting; must include patient history, provider assessment and treatment plan; follow up instructions; be adequate so that the information provided supports the assessment and plan; and must be retained in the patient's medical record and be retrievable.

**GUIDELINE NOTE 65, TELEPHONE AND EMAIL CONSULTATIONS**

*Included on all lines with evaluation & management (E&M) codes*

Telephone and email consultations (CPT 98966-98969) must meet the following criteria:

- 1) Patient must have a pre-existing relationship with the provider as demonstrated by at least one prior office visit within the past 12 months.
- 2) E-visits must be provided by a physician or licensed provider within their scope of practice.

**GUIDELINE NOTE 65, TELEPHONE AND EMAIL CONSULTATIONS (CONT'D)**

- 3) Documentation should model SOAP charting; must include patient history, provider assessment, and treatment plan; follow up instructions; be adequate so that the information provided supports the assessment and plan; must be retained in the patient's medical record and be retrievable.
- 4) Telephone and email consultations must involve permanent storage (electronic or hard copy) of the encounter.
- 5) Telephone and email consultations must meet HIPAA standards for privacy.
- 6) There needs to be a patient-clinician agreement of informed consent for E-visits by email. This should be discussed with and signed by the patient and documented in the medical record.

Examples of reimbursable telephone and email consultations include but are not limited to:

- 1) Extended counseling when person-to-person contact would involve an unwise delay.
- 2) Treatment of relapses that require significant investment of provider time and judgment.
- 3) Counseling and education for patients with complex chronic conditions.

Examples of non-reimbursable telephone and email consultations include but are not limited to:

- 1) Prescription renewal.
- 2) Scheduling a test.
- 3) Scheduling an appointment.
- 4) Reporting normal test results.
- 5) Requesting a referral.
- 6) Follow up of medical procedure to confirm stable condition, without indication of complication or new condition.
- 7) Brief discussion to confirm stability of chronic problem and continuity of present management.

**GUIDELINE NOTE 66, CERVICAL DYSPLASIA**

*Line 25*

Work up and treatment of cervical dysplasia should follow the American Society for Cervical Colposcopy and Pathology guidelines as published in the Journal of Lower Genital Tract Disease, April 2013.

**GUIDELINE NOTE 67, ENZYME REPLACEMENT THERAPY**

*Lines 147,660*

Enzyme replacement therapy for infantile Pompe's disease is included on Line 147. All other enzyme replacement therapies for inborn errors of metabolism are included on Line 660.

**GUIDELINE NOTE 68, HYSTEROSCOPIC BILATERAL FALLOPIAN TUBE OCCLUSION**

*Line 6*

Placement of permanent implants in the fallopian tubes to induce bilateral occlusion (CPT code 58565) is covered only if the procedure is done in the office setting, not in the ambulatory surgical center or hospital setting.

Hysterosalpingography (58340, 74740) is covered only for the follow-up testing after placement of permanent implants in the fallopian tubes to induce bilateral occlusion.

**GUIDELINE NOTE 69, ELECTROCONVULSIVE THERAPY (ECT)**

*Lines 7,22,26*

Electroconvulsive therapy (ECT; CPT 90870) is included on these lines for the treatment of major depressive disorder, bipolar disorder, schizophrenic disorder, or schizoaffective disorder when one or more of the following conditions are present:

- 1) Acute suicidality with high risk of acting out suicidal thoughts
- 2) Psychotic features
- 3) Rapidly deteriorating physical status due to complications from the depression, such as poor oral intake
- 4) Catatonia
- 5) History of poor response to multiple adequate trials of medications and/or combination treatments, or the patient is unable or unwilling to comply with or tolerate side effects of available medications, or has a co-morbid medical condition that prevents the use of available medications
- 6) History of good response to ECT during an earlier episode of the illness
- 7) The patient is pregnant and has severe mania or depression, and the risks of providing no treatment outweigh the risks of providing ECT

The frequency and number of treatments need to be determined by the severity of illness and by the relative benefits and risks of ECT treatment. During the course of ECT, it is important to monitor therapeutic responses and adverse effects of treatment. Continuation treatment of patients who have responded to ECT consists of treatment with antidepressant medications and/or a tapering schedule of ECT treatments. Continuation treatment reduces the risk of relapse and should be offered to all patients who respond to ECT. Continuation ECT treatments should be tapered and discontinued as the patient's clinical condition allows. Maintenance treatment with ECT is indicated to prevent recurrence of depression in patients whose remission of symptoms cannot be maintained with pharmacologic antidepressant treatment.

**GUIDELINE NOTE 70, HEART-KIDNEY TRANSPLANTS**

*Line 264*

Patients under consideration for heart/kidney transplant must qualify for each individual type of transplant under current DMAP administrative rules and transplant center criteria with the exception of any exclusions due to heart and/or kidney disease. Qualifying renal disease is limited to Stage V or VI.

**GUIDELINE NOTE 71, HIP RESURFACING**

*Line 356*

Hip resurfacing is a covered service for patients who are likely to outlive a traditional prosthesis and who would otherwise require a total hip replacement, and should only be done by surgeons with specific training in this technique.

The following criteria are required to be met for coverage of this procedure:

- A) The diagnosis of osteoarthritis or inflammatory arthritis
- B) Failure of nonsurgical management
- C) The device must be FDA approved

Patients who are candidates for hip resurfacing must not be:

- A) Patients with active or suspected infection in or around the hip joint, or sepsis
- B) Patients who are skeletally immature
- C) Patients with any vascular insufficiency, muscular atrophy, or neuromuscular disease severe enough to compromise implant stability or postoperative recovery
- D) Patients with bone stock inadequate to support the device, including severe osteopenia or a family history of severe osteoporosis or osteopenia
- E) Patients with osteonecrosis or avascular necrosis with >50% involvement of the femoral head
- F) Patients with multiple cysts of the femoral head
- G) Females of childbearing age
- H) Patients with known moderate-to-severe renal insufficiency
- I) Patients who are immunosuppressed with diseases such as AIDS or persons receiving high doses of corticosteroids
- J) Patients who are severely overweight
- K) Patients with known or suspected metal sensitivity

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 72, CONGENITAL UROLOGIC CONDITIONS**

*Lines 87,94,432,656*

The following conditions are included on these Lines 87, 94 and 432 only for children aged 18 and younger. For adults, these conditions are included on Line 656.

- ICD-10-CM Q54.0 (Hypospadias, balanic)
- ICD-10-CM Q55.22 (Retractile testicle)
- ICD-10-CM Q60.3 (Renal hypoplasia, unilateral)
- ICD-10-CM Q62.4 (Agenesis of ureter)
- ICD-10-CM Q62.5 (Duplication of ureter)
- ICD-10-CM Q62.60 (Accessory kidney)
- ICD-10-CM Q62.61 (Deviation of ureter)
- ICD-10-CM Q62.62 (Displacement of ureter)
- ICD-10-CM Q63 (Other congenital malformations of kidney)

**GUIDELINE NOTE 73, PENILE ANOMALIES**

*Lines 432,656*

Anomalies of the penis (ICD-10-CM Q54.4, Q55.5 and Q55.6) are included on Line 432 only when they

- A. Are associated with hypospadias, OR
- B. Result in documented urinary retention, OR
- C. Result in repeated urinary tract infections, OR
- D. Result in recurrent infections such as meatitis or balanitis, OR
- E. Involve 35 degrees of curvature or greater for conditions resulting in lateral or ventral curvature, OR
- F. Involve 60 degrees of rotation or greater for conditions resulting in penile torsion, OR
- G. Involve aplasia/congenital absence of the penis.

Otherwise, these diagnoses are included on Line 656.

**GUIDELINE NOTE 74, GROWTH HORMONE TREATMENT**

*Lines 40,386,467*

Treatment with growth hormone is included only for children with: pituitary dwarfism, Turner's syndrome, Prader-Willi-syndrome, Noonan's syndrome, short stature homeobox-containing gene (SHOX), chronic kidney disease (stages 3, 4, 5 or 6) and those with renal transplant. Treatment with growth hormone should continue only until adult height as determined by bone age is achieved. Treatment is not included for isolated deficiency of human growth hormone or other conditions in adults.

**GUIDELINE NOTE 75, APPLIED BEHAVIOR ANALYSIS FOR AUTISM SPECTRUM DISORDER**

*Line 193*

Applied behavioral analysis (ABA), including early intensive behavioral intervention (EIBI), represented by CPT codes 0359T-0374T, is included on Line 193 AUTISM SPECTRUM DISORDERS for the treatment of autism spectrum disorders.

ABA services are provided in addition to any rehabilitative services (e.g. physical therapy, occupational therapy, speech therapy) included in Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES that are indicated for other acute qualifying conditions.

Individuals ages 1-12

*Intensive interventions*

Specifically, EIBI (for example, UCLA/Lovaas or Early Start Denver Model), is included on this line.

For a child initiating EIBI therapy, EIBI is included for up to six months. Ongoing coverage is based on demonstrated progress towards meaningful predefined objectives (objectives should be achieved as a result of the EIBI, over and beyond gains that would be expected to arise from maturation alone) using a standardized, multimodal assessment, no more frequently than every six months. Examples of such assessments include Vineland, IQ tests (Mullen, WPPSI, WISC-R), language measures, behavior checklists (CBCL, ABC), and autistic symptoms measures (SRS).

The evidence does not lead to a direct determination of optimal intensity. Studies of EIBI ranged from 15-40 hours per week. Through Oregon's Senate Bill 365, other payers are mandated to cover a minimum of 25 hours per week of ABA. There is no evidence that increasing intensity of therapy yields improves outcomes. Studies for these interventions had a duration from less than one year up to 3 years.

*Less intensive ABA-based interventions*

If EIBI is not indicated, has been completed, or there is not sufficient progress toward multidimensional goals, then less intensive ABA-based interventions (such as parent training, play/interaction based interventions, and joint attention interventions) are included on this line to address core symptoms of autism and/or specific problem areas. Initial coverage is provided for six months. Ongoing coverage is based on demonstrated progress towards meaningful predefined objectives, with demonstration of medical appropriateness and/or emergence of new problem behaviors.

Effective interventions from the research literature had lower intensity than EIBI, usually a few hours per week to a maximum of 16 hours per week, divided into daily, twice-daily or weekly sessions, over a period of several months.

*Parent/caregiver involvement*

Parent/caregiver involvement and training is recommended as a component of treatment.

Individuals ages 13 and older

Intensive ABA is not included on this line.

Targeted ABA-based behavioral interventions to address problem behaviors, are included on this line. The quality of evidence is insufficient to support these interventions in this population. However, due to strong caregiver values and preferences and the potential for avoiding suffering and expense in dealing with unmanageable behaviors, targeted interventions may be reasonable. Behaviors eligible for coverage include those which place the member at risk for harm or create significant daily issues related to care, education, or other important functions. Ongoing coverage is based on demonstrated progress towards meaningful predefined objectives, with demonstration of medical appropriateness and/or emergence of new problem behaviors.

Very low quality evidence is available to illustrate needed intensity and duration of intervention. In the single-subject research design literature, frequency and duration of interventions were highly variable, with session duration ranging from 30 seconds to 3 hours, number of sessions ranging from a total of three to 8 times a day, and duration ranging from 1 to 20 weeks. These interventions were often conducted in inpatient or residential settings and studies often included patients with intellectual disabilities, some of which were not diagnosed with autism.

Parent/caregiver involvement and training is encouraged.

**GUIDELINE NOTE 76, DIAGNOSTIC TESTING FOR LIVER FIBROSIS TO GUIDE TREATMENT OF HEPATITIS C IN NON-CIRRHOTIC PATIENTS**

*Line 199*

Given that a fibrosis score of  $\geq F2$  is the threshold for antiviral treatment of Hepatitis C, the following are included on this line:

Imaging tests:

- Transient elastography (FibroScan®)
- Acoustic radiation force impulse imaging (ARFI) (Virtual Touch™ tissue quantification, ElastPQ)
- Shear wave elastography (SWE) (Aixplorer®)

Blood tests (only if imaging tests are unavailable):

- Enhanced Liver Fibrosis (ELF™)
- Fibrometer™
- FIBROSpect® II
- FibroSure® (FibroTest®)

If a fibrosis score of  $\geq F3$  is the threshold for antiviral treatment of Hepatitis C, one or more of the following are included on this line:

Imaging tests:

- Transient elastography (FibroScan®)
- Acoustic radiation force impulse imaging (ARFI)
- Shear wave elastography (SWE)

Magnetic resonance elastography is included on this line for  $\geq F2$  or  $\geq F3$  only when at least one imaging test (FibroScan, ARFI, and SWE) has resulted in indeterminate results, a second one is similarly indeterminate, contraindicated or unavailable, and MRE is readily available.

The following tests are not included on this line (or any other line):

- Real time tissue elastography
- Hepascore (FibroScore)

Noninvasive tests are covered no more often than once per year.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 77, TIPS PROCEDURE**

*Lines 56,217,280,334*

TIPS procedure (CPT code 37182, 37183) is included on these lines for patients who:

- A) Have failed sclerotherapy and have acute bleeding from varices; or
- B) Have failed sclerotherapy and have had 2 or more episodes of re-bleeding requiring a transfusion during a 2-week period; or
- C) Requires bleeding control from varices and surgery is contraindicated; or
- D) Are liver transplant candidates who require bleeding control from varices; or
- E) Have severe debilitating ascites or hepatic hydrothorax refractory to medical management (e.g., oral diuretics and repeated large-volume paracentesis).

**GUIDELINE NOTE 78, HEPATIC METASTASES**

*Line 315*

ICD-10-CM C78.7 Hepatic metastases are included on this line only when:

- A) Treatment of the primary tumor is covered on a funded line in accordance with the criteria in Guideline Note 12 TREATMENT OF CANCER WITH LITTLE OR NO BENEFIT;
- B) There are no other extrahepatic metastases; and,
- C) The only treatment covered is hepatectomy/resection of liver (CPT codes 47120, 47122, 47125 or 47130).

**GUIDELINE NOTE 79, BREAST RECONSTRUCTION**

*Line 191*

Breast reconstruction is only covered after mastectomy as a treatment for breast cancer or as prophylactic treatment for the prevention of breast cancer in a woman who qualifies under Guideline Note 3, and must be completed within 5 years of initial mastectomy.

Breast reconstruction may include contralateral reduction mammoplasty (CPT 19318) or contralateral mastopexy (CPT 19316). Mastopexy is only to be covered when contralateral reduction mammoplasty is inappropriate for breast reconstruction and mastopexy will accomplish the desired reconstruction result.

**GUIDELINE NOTE 80, REPAIR OF NOSE TIP**

*Line 300*

Nose tip repair (CPT 30460) is included on this line only to be used in conjunction with codes 40700, 40701, 40702 or 40720. If not done in the context of a larger cleft palate/lip surgery, then nose tip repair is only included on this line if required for correction of physical functioning.

**GUIDELINE NOTE 81, BUERGER'S DISEASE**

*Lines 236,651*

Buerger's disease (ICD-10-CM I73.1) is included on Line 236 only when ulceration or gangrene is present. Otherwise, this diagnosis is included on Line 651. ICD-10-CM I73.1 does not pair on Line 236 with revascularization procedures, bypass graft procedures, or angioplasty.

**GUIDELINE NOTE 82, EARLY INTERVENTION FOR PSYCHOSIS**

*Lines 22,26,277*

- A) These lines include "early intervention for psychosis," a multidisciplinary specialty team-based intervention that includes:
- B) Psychiatric medication management
- C) Individual counseling
- D) Family group therapy
- E) Family individual therapy

The goal of the early intervention is to minimize harms of a first outbreak of psychosis and improve long-term functioning.

**GUIDELINE NOTE 83, HIP CORE DECOMPRESSION**

*Line 356*

Hip Core Decompression (S2325) is covered only for early/pre-collapse (stage I or II; before X-ray changes are evident) avascular necrosis of the hip (femoral head and/or neck).

**GUIDELINE NOTE 84, MEDICAL NUTRITION THERAPY FOR EPILEPSY**

*Line 30*

Medical Nutrition Therapy (CPT 97802-97804) is included on this line only for training in the ketogenic diet for children with epilepsy in cases where the child has failed or not tolerated conventional therapy.

**GUIDELINE NOTE 85, ELECTIVE INDUCTION OF LABOR**

*Line 1*

Induction of labor is covered for:

- Gestational age beyond 41 weeks 0 days
- Prelabor rupture of membranes, term
- Fetal demise
- Preeclampsia, term (severe or mild)
- Eclampsia
- Chorioamnionitis
- Diabetes, pre-existing and gestational
- Placental abruption
- Preeclampsia, preterm (severe or mild)
- Severe preeclampsia, preterm
- Cholestasis of pregnancy
- Preterm, prelabor rupture of membranes;
- Gastroschisis
- Twin gestation
- Maternal medical conditions (e.g., renal disease, chronic pulmonary disease, chronic hypertension, cardiac disease, antiphospholipid syndrome)
- Gestational hypertension
- Fetal compromise (e.g. isoimmunization, oligohydramnios)
- Intrauterine growth restriction/Small for gestational age, term
- Elective purposes, >39 weeks 0 days to <41 weeks 0 days (without a medical or obstetrical indication) with a favorable cervix (for example, with a Bishop score ≥6)

Induction of labor is not covered for the following:

- Macrosomia (in the absence of maternal diabetes)

**GUIDELINE NOTE 85, ELECTIVE INDUCTION OF LABOR (CONT'D)**

- Elective purposes, >39 weeks 0 days to <41 weeks 0 days (without a medical or obstetrical indication) with an unfavorable cervix (for example, a Bishop score <6)
- Elective purposes <39 weeks (without a medical or obstetrical indication)
- Intrauterine growth restriction/Small for gestational age, preterm (without other evidence of fetal compromise)

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 86, ORGANIC MENTAL DISORDERS**

*Line 202*

There is limited evidence of the effectiveness of mental health treatment of organic mental disorders. However, case management is can be critical. Effective treatments may be available for co-morbid conditions such as mood disorders. When treating co-morbid conditions associated with organic mental disorder, those conditions should be the primary diagnosis for billing purposes. The treatment of co-morbid mental health conditions should be consistent with the treatment methods, frequency, and duration normally applied to those diagnoses. Treatment of neurologic dysfunctions that may be seen in individuals with organic mental disorder are prioritized according to the four dysfunction lines found on the Prioritized List (Lines 71, 292, 345 and 377).

**GUIDELINE NOTE 87, INFLUENZA**

*Line 398*

Treatment and post-exposure prophylaxis of influenza should comply with state and national public health recommendations.

**GUIDELINE NOTE 88, USE OF PROGESTERONE CONTAINING IUDS FOR NON-CONTRACEPTIVE INDICATIONS**

*Lines 191,420,467*

Intrauterine device (IUD) insertion and removal (CPT 58300 and 58301) are included on these lines for use only with progesterone-containing IUDs. These CPT codes are covered only for

- A) menorrhagia (ICD-10-CM N92.0-N92.2 and N92.4)
- B) for uterine protection in women taking estrogen replacement therapy after premature ovarian failure (ICD-10-CM E28.310, E28.319, E28.39, E28.8, E28.9) or menopause (ICD-10-CM N95.1) ; and
- C) for uterine protection in women taking selective estrogen receptor modulators (SERMs).

**GUIDELINE NOTE 89, REVASCULARIZATION FOR CHRONIC STABLE ANGINA**

*Line 189*

Coronary revascularization with percutaneous coronary intervention (PCI; CPT 92920-92944) or coronary artery bypass surgery (CABG; CPT 33510-33516, 33517-33530, 33533-33536) is included on this line for patients with stable angina (ICD-10-CM I20, I25.111-119, I25.701-9, I25.711-9, I25.721-9, I25.731-9, I25.751-9, I25.761-9, I25.791-9, I25.89, I25.9) whose symptoms are not controlled with optimal medical therapy for angina or who cannot tolerate such therapy.

Optimal medical therapy for angina symptom control is defined as two or more antianginals (beta-blocker, nitrate, calcium channel blocker, or ranolazine) in addition to standard treatment for coronary artery disease.

For those with left main coronary artery stenosis or three-vessel coronary artery stenosis, CABG is included on this line with or without a trial of optimal medical therapy.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 90, COGNITIVE REHABILITATION**

*Lines 92,178,196,202,285,317,345,377*

Once physical stabilization from acute brain injury has occurred, as determined by an attending physician, cognitive rehabilitation (CPT 97532) is included on this line for a three month period. This three month period does not have to be initiated immediately following stabilization from the injury. For up to 3 years following the acute event, an additional 6 visits of cognitive rehabilitation are included on this line each time the patient has a major change in status resulting in a significantly improved prognosis. Cognitive rehabilitation is not included on this line for those in a vegetative state or for those who are unable or unwilling to participate in therapy.

**GUIDELINE NOTE 91, CARIES ARRESTING MEDICAMENT APPLICATION**

*Line 343*

D1354 is limited to silver diamine fluoride applications for the treatment (rather than prevention) of caries, with a maximum of two applications per year.

**GUIDELINE NOTE 92, ACUPUNCTURE**

*Lines 1,5,202,361,401,409,461,538*

Inclusion of acupuncture (CPT 97810-97814) on the Prioritized List has the following limitations:

**Line 1 PREGNANCY**

Acupuncture pairs on Line 1 for the following conditions and codes.

*Hyperemesis gravidarum*

ICD-10-CM: O21.0, O21.1

Acupuncture pairs with hyperemesis gravidarum when a diagnosis is made by the maternity care provider and referred for acupuncture treatment for up to 12 sessions of acupressure/acupuncture per pregnancy.

*Breech presentation*

ICD-10-CM: O32.1

Acupuncture (and moxibustion) is paired with breech presentation when a referral with a diagnosis of breech presentation is made by the maternity care provider, the patient is between 33 and 38 weeks gestation, for up to 6 session per pregnancy.

*Back and pelvic pain of pregnancy*

ICD-10-CM: O99.89

Acupuncture is paired with back and pelvic pain of pregnancy when referred by maternity care provider/primary care provider for up to 12 sessions per pregnancy.

**Line 5 TOBACCO DEPENDENCE**

Acupuncture is included on this line for a maximum of 12 sessions per quit attempt up to two quit attempts per year; additional sessions may be authorized if medically appropriate.

**Line 202 CHRONIC ORGANIC MENTAL DISORDERS INCLUDING DEMENTIAS**

Acupuncture is paired with the treatment of post-stroke depression only. Treatments may be billed to a maximum of 30 minutes face-to-face time and limited to 12 total sessions per year, with documentation of meaningful improvement; patients may have additional visits authorized beyond these limits if medically appropriate.

**Line 361 SCOLIOSIS**

Acupuncture is included on this line with visit limitations as in Guideline Note 56 NON-INTERVENTIONAL TREATMENTS FOR CONDITIONS OF THE BACK AND SPINE.

**Line 401 CONDITIONS OF THE BACK AND SPINE**

Acupuncture is included on this line with visit limitations as in Guideline Note 56 NON-INTERVENTIONAL TREATMENTS FOR CONDITIONS OF THE BACK AND SPINE.

**Line 409 MIGRAINE HEADACHES**

Acupuncture pairs on Line 409 for migraine (ICD-10-CM G43.0, G43.1, G43.5, G43.7, G43.8, G43.9), for up to 12 sessions per year.

**Line 461 OSTEOARTHRITIS AND ALLIED DISORDERS**

Acupuncture pairs on Line 461 for osteoarthritis of the knee only (ICD-10-CM M17), for up to 12 sessions per year.

**\*Line 538 TENSION HEADACHES**

Acupuncture is included on Line 538 for treatment of tension headaches (ICD-10-CM G44.2), for up to 12 sessions per year.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

\*Below the current funding line.

**GUIDELINE NOTE 93, IMPLANTABLE GNRH ANALOG THERAPY**

*Line 187*

Use of drug delivery implant therapy for GnRH analogue therapy (such as histrelin) (CPT 11981-11983) is covered only when injectable depot medications (such as Lupron) are contraindicated or after such medications have been tried and complications preclude further use.

**GUIDELINE NOTE 94, PECTUS EXCAVATUM**

*Lines 400,525*

Pectus excavatum (ICD-10-CM Q67.6) is included on Line 400 only for patients with all of the following:

- 1) Severe deformity (Haller index >3.25) AND
- 2) Documented pulmonary or cardiac dysfunction demonstrated by either
  - a) Cardiac effects to include cardiac compression or displacement, bundle branch block or other cardiac pathology secondary to compression of the heart, OR
  - b) Pulmonary function studies demonstrating at least a moderately severe restrictive lung defect, AND
- 3) these conditions are reasonably expected to be relieved with surgery.

Otherwise, this condition is included on Line 525

ICD-10-CM Q79.8 is included on Line 400 only for Poland syndrome. Other diagnoses using this code are on Line 525. Surgical reconstruction of musculo-skeletal chest wall deformities associated with Poland's syndrome are only included on Line 400 when causing functional deficits.

**GUIDELINE NOTE 95, IMMUNE MODIFYING THERAPIES FOR MULTIPLE SCLEROSIS**

*Line 252*

Once a diagnosis of primary progressive or secondary progressive multiple sclerosis is reached, immune modifying therapies are no longer covered.

**GUIDELINE NOTE 96, TREATMENT OF BENIGN NEOPLASM OF URINARY ORGANS**

*Lines 215,509*

Treatment of benign urinary system tumors (ICD-10-CM D30.00-D30.02) are included on Line 215 with evidence of bleeding or urinary obstruction. Treatment of 1) oncocytoma which is >5 cm in size or symptomatic and 2) angiomyolipoma (AML) which is >5cm in women of child bearing age or in symptomatic men or women is covered. Otherwise, these diagnoses are included on Line 509.

**GUIDELINE NOTE 97, MANAGEMENT OF ACROMIOCLAVICULAR JOINT SPRAIN**

*Lines 417,605*

Sprain of acromioclavicular joint (ICD-10-CM S43.50-S43.52) is only included on Line 417 for Grade 4-6 sprains. Surgical management of these injuries is covered only after a trial of conservative therapy. Grade 1-3 acromioclavicular joint sprains are included only on Line 605.

**GUIDELINE NOTE 98, SIGNIFICANT INJURIES TO LIGAMENTS, TENDONS AND MENISCI**

*Lines 376,430,605*

Significant injuries to ligaments, tendons and/or menisci are those that result in clinically demonstrable joint instability or mechanical interference with motion. Significant injuries are covered on Line 376 or Line 430; non-significant injuries are included on Line 605.

**GUIDELINE NOTE 99, ROUTINE PRENATAL ULTRASOUND**

*Lines 1,35,37,63*

Routine ultrasound for the average risk pregnant woman is included on these lines for:

- A) One ultrasound in the first trimester for the purpose of identifying fetal aneuploidy or anomaly (between 11 and 13 weeks of gestation) and /or dating confirmation. In some instances, if a patient's LMP is truly unknown, a dating ultrasound may be indicated prior to an aneuploidy screen
- B) One ultrasound for the purpose of anatomy screening after 18 weeks gestation. For those using tobacco during pregnancy, additional counseling around smoking impacts on the fetus is included during this ultrasound.

Only one type of routine prenatal ultrasound should be covered in a single day (i.e., transvaginal or abdominal).

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 100, SMOKING AND SPINAL FUSION**

*Lines 47,150,201,255,346,361,400,476,527,556*

Non-emergent spinal arthrodesis (CPT 22532-22634) is limited to patients who are non-smoking and abstinent from all nicotine products for 6 months prior to the planned procedure, as shown by negative cotinine levels at least 6 months apart, with the second test within 1 month of the surgery date. Patients should be given access to appropriate smoking cessation therapy. Non-emergent spinal arthrodesis is defined as surgery for a patient with a lack of myelopathy or rapidly declining neurological exam.

**GUIDELINE NOTE 101, ARTIFICIAL DISC REPLACEMENT**

*Lines 346,527*

Artificial disc replacement (CPT 22856-22865) is included on these lines as an alternative to fusion only when all of the following criteria are met:

Lumbar artificial disc replacement

- A) Patients must first complete a structured, intensive, multi-disciplinary program for management of pain, if covered by the agency;
- B) Patients must be 60 years or under;
- C) Patients must meet FDA approved indications for use and not have any contraindications. FDA approval is device specific but includes:
  - Failure of at least six months of conservative treatment
  - Skeletally mature patient
  - Replacement of a single disc for degenerative disc disease at one level confirmed by patient history and imaging

Cervical artificial disc replacement

- D) Patients must meet FDA approved indications for use and not have any contraindications. FDA approval is device specific but includes:

**GUIDELINE NOTE 101, ARTIFICIAL DISC REPLACEMENT (CONT'D)**

- Skeletally mature patient
- Reconstruction of a single disc following single level discectomy for intractable symptomatic cervical disc disease (radiculopathy or myelopathy) confirmed by patient findings and imaging.

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 102, REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION**

*Line 7*

Repetitive transcranial magnetic stimulation (CPT 90867-90868) is covered only after failure of at least two antidepressants.

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 103, BONE ANCHORED HEARING AIDS**

*Lines 311,444*

Bone anchored hearing aids (BAHA, CPT 69714, 69715) are included on these lines when the following criteria are met:

- A) The patient is aged 5-20 years for implanted bone anchored hearing aids; headband mounted BAHA devices may be used for children under age 5
- B) Treatment is for unilateral severe to profound hearing loss when the contralateral ear has normal hearing with or without a hearing aid
- C) Traditional air amplification hearing aids and contralateral routing of signal (CROS) hearing aid systems are not indicated or have been tried and are found to be not effective
- D) Implantation is unilateral.

Use of BAHA for treatment of tinnitus is not covered

**GUIDELINE NOTE 104, VISCOSUPPLEMENTATION OF THE KNEE**

*Lines 430,461*

CPT 20610 and 20611 are included on these lines only for interventions other than viscosupplementation for osteoarthritis of the knee.

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 105, MEDIASTITIS**

*Lines 285,655*

ICD-10-CM J98.51 (Mediastinitis) is included on Line 285 for acute mediastinitis and on Line 655 for chronic or fibrosing mediastinitis.

**GUIDELINE NOTE 106, PREVENTIVE SERVICES**

*Lines 3,619*

Included on Line 3 are the following preventive services:

- A) US Preventive Services Task Force (USPSTF) "A" and "B" Recommendations in effect and issued prior to January 1, 2017.
  - 1) <http://www.uspreventiveservicestaskforce.org/Page/Name/uspstf-a-and-b-recommendations/>
  - 2) USPSTF "D" recommendations are not included on this line or any other line of the Prioritized List.
- B) American Academy of Pediatrics (AAP) Bright Futures Guidelines:
  - 1) <http://brightfutures.aap.org>. Periodicity schedule available at [http://www.aap.org/en-us/professional-resources/practice-support/Periodicity/Periodicity%20Schedule\\_FINAL.pdf](http://www.aap.org/en-us/professional-resources/practice-support/Periodicity/Periodicity%20Schedule_FINAL.pdf).
  - 2) Screening for lead levels is defined as blood lead level testing and is indicated for Medicaid populations at 12 and 24 months. In addition, blood lead level screening of any child between ages 24 and 72 months with no record of a previous blood lead screening test is indicated.
- C) Health Resources and Services Administration (HRSA) Women's Preventive Services - Required Health Plan Coverage Guidelines as retrieved from <http://www.hrsa.gov/womensguidelines/> on 1/1/2017.
- D) Immunizations as recommended by the Advisory Committee on Immunization Practices (ACIP):  
<http://www.cdc.gov/vaccines/schedules/hcp/index.html>

Colorectal cancer screening is included on Line 3 for average-risk adults aged 50 to 75, using one of the following screening programs:

- A) Colonoscopy every 10 years
- B) Flexible sigmoidoscopy every 5 years
- C) Fecal immunochemical test (FIT) every year
- D) Guaiac-based fecal occult blood test (gFOBT) every year

#### GUIDELINE NOTE 106, PREVENTIVE SERVICES (CONT'D)

Colorectal cancer screening for average-risk adults aged 76 to 85 is covered only for those who

- A) Are healthy enough to undergo treatment if colorectal cancer is detected, and
- B) Do not have comorbid conditions that would significantly limit their life expectancy.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### GUIDELINE NOTE 107, HYPERBARIC OXYGEN

Line 332

A course of hyperbaric oxygen treatment is included on this line subject to the following limitations:

- Codes appearing on this line from ICD-10-CM E08-E13 are included only when they are diabetic wound ulcers of the lower extremities which are Wagner grade 3 or higher (that is, involving bone or gangrenous) and show no measurable signs of healing after 30 days of adequate standard wound therapies including arterial assessment. Courses of treatment for wounds or ulcers are limited to 30 days after the initial treatment; additional 30 day treatment courses are only covered for patients with incomplete wound/infection resolution AND measurable signs of healing
- ICD-10-CM M27.2 is included on this line for osteoradionecrosis of the jaw only
- ICD-10-CM O08.0 and M60.0 are included on this line only if the infection is a necrotizing soft-tissue infection
- ICD-10-CM S07, S17, S38, S47.1, S47.2, S47.9, S57, S67, S77, S87, S97, T79.A are included on this line only for posttraumatic crush injury of Gustilo type III B and C
- ICD-10-CM T66.XXXA-T66.XXXD and L59.8 are included on this line only for osteoradionecrosis and soft tissue radiation injury
- ICD-10-CM T86.82, T82.898, T82.9, T83.89, T83.9, T84.89, T84.9, T85.89, T85.9 are included on this line only for compromised myocutaneous flaps

#### GUIDELINE NOTE 108, CONTINUOUS GLUCOSE MONITORING

Line 8

Real-time continuous glucose monitoring (CGM) is included on Line 8 for:

- A) Adults with type 1 diabetes mellitus not on insulin pump management:
  - 1) Who have received or will receive diabetes education specific to the use of CGM AND
  - 2) Who have used the device for at least 50% of the time at their first follow-up visit AND
  - 3) Who have baseline HbA1c levels greater than or equal to 8.0%, frequent or severe hypoglycemia, or impaired awareness of hypoglycemia (including presence of these conditions prior to initiation of CGM).
- B) Adults with type 1 diabetes on insulin pump management (including the CGM-enabled insulin pump):
  - 1) Who have received or will receive diabetes education specific to the use of CGM AND
  - 2) Who have used the device for at least 50% of the time at their first follow-up visit.
- C) Women with type 1 diabetes who are pregnant or who plan to become pregnant within six months without regard to HbA1c levels.
- D) Children and adolescents under age 21 with type 1 diabetes:
  - 1) Who have received or will receive diabetes education specific to the use of CGM AND
  - 2) Who have used the device for at least 50% of the time at their first follow-up visit.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### GUIDELINE NOTE 109, VERTEBROPLASTY, KYPHOPLASTY, AND SACROPLASTY

Line 476

Vertebroplasty and kyphoplasty are not included on this line (or any other line) for the treatment of routine osteoporotic compression fractures.

Vertebroplasty and kyphoplasty are only included on this line for the treatment of vertebral osteoporotic compression fractures when they are considered non-routine and meet all of the following conditions:

- A) The patient is hospitalized under inpatient status due to pain that is primarily related to a well-documented acute fracture, and
- B) The severity of the pain prevents unassisted ambulation, and
- C) The pain is not adequately controlled with oral or transcutaneous medication, and
- D) The patient must have failed an appropriate trial of conservative management.

Sacroplasty is not included on these or any lines of the Prioritized List for coverage consideration.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### GUIDELINE NOTE 110, CHRONIC PELVIC INFLAMMATORY CONDITIONS

Lines 51,529

Chronic pelvic inflammatory conditions (ICD-10-CM N70.91-N70.93, N71.9, N73.2, N73.4, N73.5, N73.8, N73.9, N74) are included only on Line 529; acute conditions are included on Line 51.

**GUIDELINE NOTE 111, INTRA-AORTIC BALLOON PUMPS**

Line 69

Intra-aortic balloon pumps (CPT 33967-33974) are included on this line only for use in cardiogenic shock.

**GUIDELINE NOTE 112, LUNG VOLUME REDUCTION SURGERY**

Line 283

Lung volume reduction surgery (LVRS, CPT 32491, 32672) is included on Line 283 only for treatment of patients with radiological evidence of severe bilateral upper lobe predominant emphysema (ICD-10-CM J43.9) and all of the following:

- A) BMI  $\leq 31.1$  kg/m<sup>2</sup> (men) or  $\leq 32.3$  kg/m<sup>2</sup> (women)
- B) Stable with  $\leq 20$  mg prednisone (or equivalent) dose a day
- C) Pulmonary function testing showing
  - 1) Forced expiratory volume in one second (FEV<sub>1</sub>)  $\leq 45\%$  predicted and, if age 70 or older, FEV<sub>1</sub>  $\geq 15\%$  predicted value
  - 2) Total lung capacity (TLC)  $\geq 100\%$  predicted post-bronchodilator
  - 3) Residual volume (RV)  $\geq 150\%$  predicted post-bronchodilator
- D) PCO<sub>2</sub>  $\leq 60$  mm Hg (PCO<sub>2</sub>  $\leq 55$  mm Hg if 1-mile above sea level)
- E) PO<sub>2</sub>  $\geq 45$  mm Hg on room air (PO<sub>2</sub>  $\geq 30$  mm Hg if 1-mile above sea level)
- F) Post-rehabilitation 6-min walk of  $\geq 140$  m
- G) Non-smoking and abstinence from all nicotine products for 6 months prior to surgery, as shown by negative cotinine levels at least 6 months apart, with the second test within 1 month of the surgery date.

The procedure must be performed at an approved facility (1) certified by the Joint Commission on Accreditation of Healthcare Organizations (Joint Commission) under the LVRS Disease Specific Care Certification Program or (2) approved as Medicare lung or heart-lung transplantation hospitals. The patient must have approval for surgery by pulmonary physician, thoracic surgeon, and anesthesiologist post-rehabilitation. The patient must have approval for surgery by cardiologist if any of the following are present: unstable angina; left-ventricular ejection fraction (LVEF) cannot be estimated from the echocardiogram; LVEF  $<45\%$ ; dobutamine-radiolabeled cardiac scan indicates coronary artery disease or ventricular dysfunction; arrhythmia ( $>5$  premature ventricular contractions per minute; cardiac rhythm other than sinus; premature ventricular contractions on EKG at rest).

**GUIDELINE NOTE 113, DISEASES OF LIPS**

Lines 206,580

ICD-10-CM K13.0 (Diseases of lips) is included on Line 206 only for treatment of abscess or cellulitis of the lips. All other diagnoses coded using K13.0 are included on Line 580.

**GUIDELINE NOTE 114, FEMOROACETABULAR IMPINGEMENT SYNDROME**

Line 356

ICD-10-CM M25.85 (Other specified joint disorders, hip), M24.15 (Other articular cartilage disorders, hip) and M76.2 (Iliac crest spur) pair with CPT codes 29914-29916 (Arthroscopy, hip, surgical) and are included on Line 356 only for the diagnosis and treatment of femoroacetabular impingement syndrome.

Surgery for femoroacetabular impingement syndrome is included on this line only for patients who meet all of the following criteria:

- A) Adult patients, or adolescent patients who are skeletally mature with documented closure of growth plates; and
- B) Other sources of pain have been ruled out (e.g., lumbar spine pathology, SI joint dysfunction, sports hernia); and
- C) Pain unresponsive to physical therapy and other non-surgical management and conservative treatments (e.g., restricted activity, cortisone injections, nonsteroidal anti-inflammatory drugs) of at least three months duration, or conservative therapy is contraindicated; and
- D) Moderate-to-severe persistent hip or groin pain that significantly limits activity and is worsened by flexion activities (e.g., squatting or prolonged sitting); and
- E) Positive impingement sign (i.e., sudden pain on 90 degree hip flexion with adduction and internal rotation or extension and external rotation); and
- F) Radiographic confirmation of FAI (e.g., pistol-grip deformity, alpha angle greater than 50 degrees, coxa profunda, and/or acetabular retroversion); and
- G) Do not have advanced osteoarthritis (i.e., Tönnis grade 2 or 3) and/or severe cartilage damage (i.e., Outerbridge grade III or IV).

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 115, EXTRACORPOREAL PHOTOPHERESIS**

Lines 158,313

Extracorporeal photopheresis (CPT 36522) is included on Line 158 for treatment of chronic T-cell lymphoma (ICD-10-CM C84.0 and C84.1) which is:

- A) stage III or IVA
- B) erythrodermic

**GUIDELINE NOTE 115, EXTRACORPOREAL PHOTOPHERESIS (CONT'D)**

- C) not responsive to other therapy

Extracorporeal photopheresis (CPT 36522) is included on Line 313 for treatment of chronic graft-versus-host disease (ICD-10-CM T86.0) which

- A) is steroid refractory, steroid dependent or the patient is unable to tolerate corticosteroid therapy  
B) primarily affects skin or mucosal membranes (mouth and/or eye disease)

**GUIDELINE NOTE 116, INTRAOCULAR STEROID TREATMENTS**

*Lines 96,360,439*

Intraocular steroid treatments (CPT 67027, 67028) are included on Line 360 for pairing with uveitis (ICD-10-CM H30.0, H30.1, H30.89, H30.9, H44.11) when the following conditions are met: uveitis is chronic, non-infectious, and there has been appropriate trial and failure, or intolerance of therapy, with local and systemic corticosteroids and/or immunosuppressive agents.

Intraocular steroid treatments (CPT 67027, 67028) are included on Line 96 for treating chronic diabetic macular edema (ICD-10-CM E11.311) only when there has been insufficient response to anti-VEGF therapies, and only when FDA approved treatments are utilized.

Intraocular steroid treatments (CPT 67027, 67028) are only included on Line 439 for treatment of macular edema due to:

- A) Central retinal vein occlusion (ICD-10-CM H34.81) in those individuals who have failed anti-VEGF therapy.  
B) Branch retinal vein occlusion (ICD-10-CM H34.83) when treatment with laser photocoagulation has not been beneficial, or treatment with laser photocoagulation is not considered suitable because of the extent of macular hemorrhage in those individuals who have failed anti-VEGF therapy.

**GUIDELINE NOTE 117, REMOVAL OF TORI AND EXCISION OF HYPERPLASTIC TISSUE**

*Line 451*

D7472 and D7473, and D7970 are included on this line only when used in conjunction with making a prosthesis.

**GUIDELINE NOTE 118, OBSTRUCTIVE SLEEP APNEA DIAGNOSIS AND TREATMENT FOR CHILDREN**

*Line 203*

Obstructive sleep apnea (OSA) in children (18 or younger) must be diagnosed by

- A) nocturnal polysomnography with an AHI >5 episodes/h or AHI>1 episodes/h with history and exam consistent with OSA, OR  
B) nocturnal pulse oximetry with 3 or more SpO2 drops <90% and 3 or more clusters of desaturation events, or alternatives desaturation (>3%) index >3.5 episodes/h, OR  
C) use of a validated questionnaire (such as the Pediatric Sleep Questionnaire or OSA 18), OR  
D) consultation with a sleep medicine specialist.

Polysomnography and/or consultation with a sleep medicine specialist to support the diagnosis of OSA and/or to identify perioperative risk is recommended for

- A) high risk children (i.e. children with cranio-facial abnormalities, neuromuscular disorders, Down syndrome, etc.)  
B) children with equivocal indications for adenotonsillectomy (such as discordance between tonsillar size on physical examination and the reported severity of sleep-disordered breathing),  
C) children younger than three years of age

Adenotonsillectomy is an appropriate first line treatment for children with OSA. Weight loss is recommended in addition to other therapy in patients who are overweight or obese. Adenoidectomy without tonsillectomy is only covered when a child with OSA has previously had a tonsillectomy, when tonsillectomy is contraindicated, or when tonsillar hypertrophy is not present. More complex surgical treatments are only included on this line for children with craniofacial anomalies.

Intranasal corticosteroids are an option for children with mild OSA in whom adenotonsillectomy is contraindicated or for mild postoperative OSA.

CPAP is covered for a 3 month trial for children through age 18 who have

- A) undergone surgery or are not candidates for surgery, AND  
B) have documented residual sleep apnea symptoms (sleep disruption and/or significant desaturations) with residual daytime symptoms (daytime sleepiness or behavior problems)

CPAP will be covered for children through age 18 on an ongoing basis if:

- There is documentation of improvement in sleep disruption and daytime sleepiness and behavior problems with CPAP use
- Annual re-evaluation for CPAP demonstrates ongoing clinical benefit and compliance with use, defined as use of CPAP for at least four hours per night on 70% of the nights in a consecutive 30 day period

#### **GUIDELINE NOTE 119, CAROTID ENDARTERECTOMY**

*Line 414*

Carotid endarterectomy is included on Line 414 for patients in the following groups:

- Symptomatic<sup>1</sup> with 70-99% carotid artery stenosis but without near occlusion.
- Symptomatic with 50 – 69% stenosis despite optimal medical management
- Asymptomatic with at least 60% stenosis only for those who do not tolerate (or have contraindications to) best current medical therapy

Carotid endarterectomy is not included on Line 414 for patients in the following groups:

- Patients with near occlusion
- Symptomatic<sup>1</sup> patients with less than 50% carotid stenosis

<sup>1</sup>Symptomatic patients are those who have had a recent transient ischemic attack or ischemic stroke.

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

#### **GUIDELINE NOTE 120, PEDIATRIC TRIGGER THUMB**

*Line 376*

ICD-10-CM M65.31 is included on Line 376 for treatment of pediatric trigger thumb only. Surgical treatment should be reserved for trigger thumb that does not spontaneously resolve within 48 months of diagnosis. Immediate surgery may be considered for bilateral trigger thumb or trigger thumb with locking symptoms.

#### **GUIDELINE NOTE 121, CONCUSSION AND POST CONCUSSION SYNDROME**

*Lines 92,202,609*

ICD-10-CM S06.0X0, S06.2X0 and S06.300 are included on Line 92 only for concussions with symptoms that persist for more than 7 days but less than 3 months; otherwise, these diagnoses are included on Line 609. When concussion symptoms last for more than 3 months, the diagnosis of post-concussive syndrome (ICD-10-CM F07.81) should be used, which is included on Line 202.

#### **GUIDELINE NOTE 122, ORAL HEALTH RISK ASSESSMENT IN MEDICAL SETTINGS**

*Line 3*

D0191 is limited to children under age 6 and requires an additional specific oral health risk assessment using a standardized tool, such as AAP Bright Futures, and should be performed by a provider who has successfully completed an approved training program (such as First Tooth or Smiles for Life).

#### **GUIDELINE NOTE 123, DENTAL FILLINGS FOR POSTERIOR TEETH**

*Line 343*

For dental fillings in posterior teeth, amalgam is preferred for extensive restorations. If amalgam is unavailable or contraindicated, composite is acceptable.

#### **GUIDELINE NOTE 124, ALCOHOL SEPTAL ABLATION**

*Line 99*

Alcohol septal ablation (CPT 93583) is included on Line 99 only for adult patients with hypertrophic cardiomyopathy when all of the following conditions are met:

- A) Severe heart failure symptoms (New York Heart Association [NYHA] class III or IV)
- B) Severe symptoms refractory to optimal medical management
- C) LVOT obstruction is present
- D) Surgery is contraindicated or has unacceptable risk due to serious comorbidities or advanced age.
- E) No concomitant disease is present that independently warrants surgical correction in whom surgical myectomy can be performed as part of the operation.
- F) The ablation is performed at an experienced center

#### **GUIDELINE NOTE 125, CAROTID ARTERY STENTING**

*Lines 317,414*

Carotid artery stenting (CPT 37215-37217) is included on Lines 317 and 414 for patients who have not had a disabling stroke (modified Rankin scale  $\geq 3$ ) AND

**GUIDELINE NOTE 125, CAROTID ARTERY STENTING (CONT'D)**

- A) who are at high risk for complications during carotid endarterectomy (CEA) due to significant comorbidities and/or anatomic risk factors (i.e., recurrent stenosis and/or previous radical neck dissection) and who also have symptomatic (recent transient ischemic attack or ischemic stroke) carotid artery stenosis >50% OR
- B) who are at high risk for complications during CEA due to significant comorbidities and/or anatomic risk factors and have asymptomatic carotid artery stenosis ≥80% only if best current medical therapy is not tolerated or contraindicated.

**GUIDELINE NOTE 126, APPLIED BEHAVIOR ANALYSIS INTERVENTIONS FOR SELF-INJURIOUS BEHAVIOR**

*Line 436*

Targeted ABA-based interventions towards self-injurious problem behaviors are included on this line when meeting criteria as defined in Guideline Note 75 APPLIED BEHAVIOR ANALYSIS FOR AUTISM SPECTRUM DISORDER.

**GUIDELINE NOTE 127, GENDER DYSPHORIA**

*Line 312*

Hormone treatment with GnRH analogues for delaying the onset of puberty and/or continued pubertal development is included on this line for gender questioning children and adolescents. This therapy should be initiated at the first physical changes of puberty, confirmed by pubertal levels of estradiol or testosterone, but no earlier than Tanner stages 2-3. Prior to initiation of puberty suppression therapy, adolescents must fulfill eligibility and readiness criteria and must have a comprehensive mental health evaluation. Ongoing psychological care is strongly encouraged for continued puberty suppression therapy.

Cross-sex hormone therapy is included on this line for treatment of adolescents and adults with gender dysphoria who meet appropriate eligibility and readiness criteria. To qualify for cross-sex hormone therapy, the patient must:

- A) have persistent, well-documented gender dysphoria
- B) have the capacity to make a fully informed decision and to give consent for treatment
- C) have any significant medical or mental health concerns reasonably well controlled
- D) have a comprehensive mental health evaluation provided in accordance with Version 7 of the World Professional Association for Transgender Health (WPATH) Standards of Care ([www.wpath.org](http://www.wpath.org)).

Sex reassignment surgery is included for patients who are sufficiently physically fit and meet eligibility criteria. To qualify for surgery, the patient must:

- A) have persistent, well documented gender dysphoria
- B) for genital surgeries, have completed twelve months of continuous hormone therapy as appropriate to the member's gender goals unless hormones are not clinically indicated for the individual
- C) have completed twelve months of living in a gender role that is congruent with their gender identity unless a medical and a mental health professional both determine that this requirement is not safe for the patient
- D) have the capacity to make a fully informed decision and to give consent for treatment
- E) have any significant medical or mental health concerns reasonably well controlled
- F) for breast/chest surgeries, have one referral from a mental health professional provided in accordance with version 7 of the WPATH Standards of Care.
- G) For genital surgeries, have two referrals from mental health professionals provided in accordance with version 7 of the WPATH Standards of Care.

Electrolysis (CPT 17380) and laser hair removal (CPT 17110, 17111) are only included on this line as part of pre-surgical preparation for chest or genital surgical procedures also included on this line. These procedures are not included on this line for facial or other cosmetic procedures or as pre-surgical preparation for a procedure not included on this line.

Mammoplasty (CPT 19316, 19324-19325, 19340, 19342, 19350) is only included on this line when 12 continuous months of hormonal (estrogen) therapy has failed to result in breast tissue growth of Tanner Stage 5 on the puberty scale OR there is any contraindication to, intolerance of or patient refusal of hormonal therapy.

Revisions to surgeries for the treatment of gender dysphoria are only covered in cases where the revision is required to address complications of the surgery (wound dehiscence, fistula, chronic pain directly related to the surgery, etc.). Revisions are not covered solely for cosmetic issues.

Pelvic physical therapy (CPT 97001, 97001, 97110, 97140, and 97530) is included on this line only for pre- and post-operative therapy related to genital surgeries also included on this line and as limited in Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES.

**GUIDELINE NOTE 128, FOREIGN BODIES IN THE GI TRACT**

*Lines 41, 498*

ICD-10-CM T18.2XXD, T18.3XXD, T18.4XXD, T18.5XXD, T18.8XXD, T18.9XXD) are included on Line 41 only when hazardous objects are involved that are likely to cause perforation (e.g. sharp objects >2 inches, neodymium magnets, button batteries) or obstruction.

**GUIDELINE NOTE 129, FECAL INCONTINENCE**

*Lines 71,526*

ICD-10-CM R15.9 (Full incontinence of feces) is included on Line 71 only for supportive equipment (e.g. diapers, gloves). Surgical treatment for fecal incontinence is included on Line 526 DISORDERS OF FUNCTION OF STOMACH AND OTHER FUNCTIONAL DIGESTIVE DISORDERS

**GUIDELINE NOTE 130, BLEPHAROPLASTY**

*Line 469*

Blepharoplasty is covered when 1) visual fields demonstrate an absolute superior defect to within 15 degrees of fixation, 2) upper eyelid position contributes to difficulty tolerating a prosthesis in an anophthalmic socket, 3) essential blepharospasm or hemifacial spasm is present, OR 4) when there is significant ptosis in the downgaze reading position.

**GUIDELINE NOTE 131, HYPOTONY**

*Lines 285,652*

ICD-10-CM H44.40-H44.439 (hypotony of the eye) are only included on Line 285 when resulting from a complication of a procedure. Non-procedure related cases are included on Line 652.

**GUIDELINE NOTE 132, ACNE CONGLOBATA**

*Line 373*

Acne conglobata is only included on Line 373 if it involves recurrent abscesses or communicating sinuses.

**GUIDELINE NOTE 133, ACUTE PERIPHERAL MOTOR AND DIGITAL NERVE INJURY**

*Lines 208,425,507,534*

Repair of acute (<6 months) peripheral nerve injuries are included on Lines 208 and 425. Non-surgical medical care of these injuries are included on Line 507. Surgical repair of chronic nerve injuries are included on Line 534.

**GUIDELINE NOTE 134, NEONATAL NASOLACRIMAL DUCT OBSTRUCTION**

*Lines 393,508*

Probing of nasolacrimal duct (CPT 68810-68840) is included on Line 393 only for children 12 months of age and older who have failed conservative management (e.g. topical antibiotics, Crigler massage) and for children younger than 12 months of age with multiple episodes of purulent infections.

**GUIDELINE NOTE 135, FIBROMYALGIA**

*Line 528*

Fibromyalgia (ICD-10-CM M79.7) treatment should consist of a multi-modal approach, which should include two of more of the following:

- A) medications other than opioids
- B) exercise advice/programs
- C) cognitive behavioral therapy.

Care should be provided in the primary care setting. Referrals to specialists are generally not required. Use of opioids should be avoided due to evidence of harm in this condition.

**GUIDELINE NOTE 136, COLLAPSED VERTEBRA**

*Lines 150,476*

Diagnosis codes appearing on this line for collapsed vertebra (in the ICD-10-CM M48.5 series) are included on Line 150 for a fracture that qualified for trauma system entry or a fracture with spinal cord injury.

**GUIDELINE NOTE 137, BENIGN BONE TUMORS**

*Lines 400,556*

Treatment of benign conditions of joints (ICD-10-CM D18.09 synovial hemangioma, D17.79 lipoma arborescens, D48.1 tenosynovial giant cell tumor, M67.8 synovial chondromatosis and M12.2 villonodular synovitis) are included on Line 400 for those conditions only when there are significant functional problems of the joint due to size, location, or progressiveness of the disease. Treatment of all other benign joint conditions are included on Line 556.

Treatment of benign tumors of bones (ICD-10-CM D16.00-D16.9, K09.0, K09.1, M27.1, M27.40, M27.49, M85.40-M85.69) are included on Line 400 for those neoplasms associated with pathologic fractures, at high risk of fracture, or which cause function problems

3-22-2018 (Includes 1-5-2018 Revisions)

Page GN-33

**GUIDELINE NOTE 137, BENIGN BONE TUMORS (CONT'D)**

including impeding joint function due to size, causing nerve compression, have malignant potential or are considered precancerous. Treatment of all other benign bone tumors are included on Line 556

**GUIDELINE NOTE 138, OBSTRUCTIVE AND REFLUX UROPATHY**

*Line 21*

ICD-10-CM N13.9 (Obstructive and reflux uropathy unspecified) appears on this line for pediatric populations only.

**GUIDELINE NOTE 139, FRENOTOMY FOR TONGUE-TIE IN NEWBORNS**

*Lines 18,593*

Ankyloglossia (ICD-10-CM Q38.1 is included on Line 18 for pairing with frenotomy (CPT 41010, CDT D7960) only when it interferes with breastfeeding. Otherwise, Q38.1 and CPT 41010 are included on Line 593.

**GUIDELINE NOTE 140, BREASTFEEDING SUPPORT AND SUPPLIES**

*Line 3*

Breast pumps and supplies are covered for postpartum women when a pump is necessary to establish or maintain milk production in order to maximize availability of breast milk to the baby.

For cases in which there is a medical indication for breast pumps, the pumps should be supplied whenever possible within 24 hours to allow for continued milk production.

Lactation support services (including education and counseling by trained providers) are covered for pregnant and postpartum women (for six months postpartum).

**GUIDELINE NOTE 141, LARYNGEAL STENOSIS OR PARALYSIS; DYSPHONIA**

*Lines 66,516*

Laryngeal and vocal cord paralysis (ICD-10-CM J38.01 and J38.02) are included on line Line 66 if associated with recurrent aspiration pneumonia (unilateral or bilateral) or airway obstruction (bilateral). Vocal cord paralysis is included on line 70 for children 18 and under with dysphonia or dysphagia persisting for at least twelve months. Treatment of hoarseness and dysphonia in adults are included only on Line 516. Laryngeal stenosis (ICD-10-CM J38.6) is included on Line 66 only if it causes airway obstruction; otherwise it is included on Line 516.

**GUIDELINE NOTE 142, STEREOTACTIC BODY RADIATION THERAPY**

*Line 263*

Stereotactic body radiation therapy (CPT 32701, 77373, 77435) is included on Line 263 only for early stage non-small cell lung cancer in medically inoperable patients.

**GUIDELINE NOTE 143, TREATMENT OF UNILATERAL HEARING LOSS**

*Lines 311,444*

Unilateral hearing loss treatment is Included on these lines only for children aged 20 and younger with the following conditions:

1. For mild to moderate sensorineural unilateral hearing loss (defined as 26-70 dB hearing loss at 500, 1000 and 2000 Hz), first line intervention should be a conventional hearing aid, with second line therapy being contralateral routing of signal (CROS) system
2. For severe to profound unilateral sensorineural hearing loss (defined as 71 dB hearing loss or greater at 500, 1000 and 2000 Hz), first line therapy should be a contralateral routing of signal (CROS) system with second line therapy being a bone anchored hearing aid (BAHA). BAHA SoftBand therapy may be first line therapy for children under age 5 or patients with severe ear deformities (e.g. microstia, severe canal atresia).

Cochlear implants are not included on these lines for unilateral hearing loss per Guideline Note 31 COCHLEAR IMPLANTATION.

**GUIDELINE NOTE 144, PROTON PUMP INHIBITOR THERAPY FOR GASTROESOPHAGEAL REFLUX DISEASE (GERD)**

*Lines 314,380,511*

Short term treatment (up to 8 weeks) of GERD without Barrett's (ICD-10-CM K20.8, K20.9, K21.0, K21.9) with proton pump inhibitor therapy is included on Line 380.

Long term proton pump inhibitor therapy is included on Line 380 for Barrett's esophagus (ICD-10-CM K22.70). Long term treatment is included on Line 511 and on Line 314 for Barrett's esophagus with dysplasia (ICD-10-CM K22.71).

**GUIDELINE NOTE 145, TREATMENTS FOR BENIGN PROSTATE ENLARGEMENT WITH LOWER URINARY TRACT SYMPTOMS**

*Line 327*

For men with lower urinary tract symptoms (LUTS) due to benign prostate enlargement, coverage of surgical procedures is recommended only if symptoms are severe, and if drug treatment and conservative management options have been unsuccessful or are not appropriate.

The following interventions for benign prostate enlargement are not included on Line 327 due to lack of evidence of effectiveness:

- Botulinum toxin
- HIFU (High Intensity Focused Ultrasound)
- TEAP (Transurethral Ethanol Ablation of the Prostate)
- Prostatic urethral lifts
- Laser coagulation (for example, VLAP/ILC)
- Prostatic artery embolization

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 146, ABLATION PROCEDURES FOR ATRIAL FIBRILLATION**

*Line 347*

AV nodal ablation (CPT 33250, 33251, 33261, 93650) pairs with atrial fibrillation (ICD-10-CM I48.0, I48.1, I48.2, I48.91) only for patients with inadequate ventricular rate control resulting in symptoms, left ventricular systolic dysfunction or substantial risk of left ventricular systolic dysfunction, when pharmacological therapy for rate control is ineffective or not tolerated

Transcatheter pulmonary vein isolation (93656-93657) pairs with atrial fibrillation (ICD-10-CM I48.0, I48.1, I48.2, I48.91) only for patients who remain symptomatic from atrial fibrillation despite rate control medications and antiarrhythmic medications.

Surgical ablation (pulmonary vein isolation or Maze procedure) (CPT 33254-33259, 33265, 33266) only pairs with atrial fibrillation (ICD-10-CM I48.0, I48.1, I48.2, I48.91) at the time of other cardiac surgery for patients who remain symptomatic despite rate control medications.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 147, IVC FILTERS FOR ACTIVE PULMONARY EMBOLISM (PE)/DEEP VEIN THROMBOSIS (DVT)**

*Lines 1,79,214,280,285*

Inferior vena cava (IVC) filter placement (CPT 37191) is included on these lines for patients with active deep vein thrombosis/pulmonary embolism (DVT/PE) for which anticoagulation is contraindicated. IVC filter placement is not included on these lines for patients with DVT who are candidates for anticoagulation.

Retrieval of removable IVC filters (CPT 37193) is included on these lines when the benefits of removal outweigh the harms.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 148, BIOMARKER TESTS OF CANCER TISSUE**

*Lines 157,184,191,230,263,271,329*

The use of multiple molecular testing to select targeted cancer therapy (CPT 81504) is included on the Services recommended for non-coverage table.

For breast cancer, Oncotype Dx testing (CPT 81519, HCPCS S3854) is included on Line 191 only for early stage breast cancer when used to guide adjuvant chemotherapy treatment decisions for women who are lymph node negative. Oncotype Dx is not included on this line for lymph node-positive breast cancer. Mammaprint, ImmunoHistoChemistry 4 (IHC4), and Mammostrat for breast cancer are included on the Services recommended for noncoverage table.

For melanoma, BRAF gene mutation testing (CPT 81210) is included on Line 230.

For lung cancer, epidermal growth factor receptor (EGFR) gene mutation testing (CPT 81235) is included on Line 263 only for non-small cell lung cancer. KRAS gene mutation testing (CPT 81275) is not included on this line.

For colorectal cancer, KRAS gene mutation testing (CPT 81275) is included on Line 157. BRAF (CPT 81210) and Oncotype DX are not included on this line. Microsatellite instability (MSI) is included on the Services recommended for noncoverage table.

For bladder cancer, Urovysion testing is included on Services recommended for noncoverage table.

**GUIDELINE NOTE 148, BIOMARKER TESTS OF CANCER TISSUE (CONT'D)**

For prostate cancer, Oncotype DX is not included on Line 329 and Prolaris is included on the Services recommended for noncoverage table.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 149, SCLEROTHERAPY OF FLUID COLLECTIONS**

*Lines 168,225,293,421,422,478,542,554,564,590,601,628*

Sclerotherapy for fluid collections (CPT 49185) is included on these lines only for the treatment of cysts, seromas or lymphoceles which are causing bleeding, infection, severe pain, organ torsion, or organ dysfunction.

**GUIDELINE NOTE 150, FETAL MRI**

*Line 1*

Fetal MRI (CPT 74712-74713) is included on this line only when all of the following conditions are met:

- A) Abnormalities are found on fetal ultrasound performed by an experienced sonologist which cannot be adequately further evaluated by 2D or 3D ultrasound
- B) The information obtained by fetal MRI is necessary for decisions about fetal or neonatal therapy, delivery planning, or to advise a family about prognosis
- C) The fetus is 18 weeks gestational age or older
- D) The MRI is performed and interpreted at a center with technicians and radiologists who are either trained or highly experienced in fetal MRI and which has appropriate MRI equipment, with a minimum of a 1.5 Tesla magnet.

**GUIDELINE NOTE 151, CARDIAC TRANSPLANT GENETIC TESTING FOR TRANSPLANT REJECTION**

*Lines 241,264*

Genetic testing for cardiac transplant rejection (CPT 81595) is included on these lines only for patients at least 1 year post transplant who are without clinical signs of rejection.

**GUIDELINE NOTE 152, UNSPECIFIED CONDUCT DISORDER**

*Lines 419,477*

ICD-10-CM F91.9 (Conduct disorder, unspecified) is included on Line 419 only for children ages 5 and younger who cannot be diagnosed with a more specific mental health diagnosis. This diagnosis is included on Line 477 for older children and adolescents.

**GUIDELINE NOTE 153, PLANNED OUT-OF-HOSPITAL BIRTH**

*Lines 1,2*

Planned out-of-hospital birth is included on these lines when appropriate risk assessments are performed, and the consultation and transfer criteria are followed, and no high risk coverage exclusion criteria exist. Risk assessment should be done initially when planning the location of birth, and updated throughout pregnancy, labor, and delivery to determine if out-of-hospital birth is still appropriate.

The clinical and/or diagnostic assessment of each criterion, with the exception of those marked with an asterisk, is necessary for planned out-of-hospital birth to be included on these lines. (Criteria marked with an asterisks may not be known or not be pertinent if there is no clinical indication for concern and additional diagnostic testing is not indicated.)

An ultrasound is required to rule out certain risk criteria (e.g. multiple gestation, placenta previa, and life threatening congenital anomalies). Certain risk criteria require serial measurements such as fundal height and blood pressure.

If a woman refuses a required clinical or diagnostic assessment, then ascertainment of her risk status is unknowable and she does not meet criteria for coverage for an out-of-hospital birth.

Documentation of continuing appropriate risk assessment and routine prenatal care is required.

High-risk coverage exclusion criteria:

*Complications in a previous pregnancy:*

- Maternal surgical history
- Cesarean section or other hysterotomy
  - Uterine rupture
  - Retained placenta requiring surgical removal
  - Fourth-degree laceration without satisfactory functional recovery

**GUIDELINE NOTE 153, PLANNED OUT-OF-HOSPITAL BIRTH (CONT'D)**

Maternal medical history

- Pre-eclampsia requiring preterm birth
- Eclampsia
- HELLP syndrome

Fetal and placental

- Unexplained stillbirth/neonatal death or previous death related to intrapartum difficulty
- Baby with neonatal encephalopathy
- Placental abruption with adverse outcome

*Complications of current pregnancy:*

Maternal

- Induction of labor
- Prelabor rupture of membranes > 24 hours
- Pre-existing chronic hypertension; Pregnancy-induced hypertension with diastolic blood pressure greater than or equal to 90 mmHg or systolic blood pressure greater than or equal to 140 mmHg on two consecutive readings taken at least 30 minutes apart
- Unknown group B strep carrier state
- Lack of informed consent on group B strep prophylaxis, if mother is Group B strep positive.
- Eclampsia or pre-eclampsia
- Anemia – hemoglobin less than 8.5 g/dL
- Thrombocytopenia (platelets <100,000)
- Thrombosis/thromboembolism or other maternal bleeding disorder\*
- Maternal mental illness requiring inpatient care\*
- Drug or alcohol use with high risk for adverse effects to fetal or maternal health
- Unknown, or positive, syphilis, HIV, or Hepatitis B status
- Current active infection of varicella at the time of labor; rubella infection anytime during pregnancy; active infection (outbreak) of genital herpes at the time of labor\*
- Refractory hyperemesis gravidarum\*
- Diabetes, type I or II, uncontrolled gestational diabetes, or gestational diabetes controlled with medication

Placental

- Low lying placenta within 2 cm or less of cervical os at term; placenta previa, vasa previa
- Placental abruption/abnormal bleeding
- Recurrent antepartum hemorrhage
- Uteroplacental insufficiency\*

Fetal

- Gestational age - preterm or postdates (defined as gestational age < 37 weeks + 0 days or > 41 weeks + 6 days)
- Multiple gestation
- Non-cephalic fetal presentation
- IUGR (defined as fetal weight less than fifth percentile using ethnically-appropriate growth tables, or concerning reduced growth velocity on ultrasound)\*
- Oligohydramnios or polyhydramnios\*
- Abnormal fetal heart rate/Doppler/surveillance studies
- Blood group incompatibility with atypical antibodies, or Rh sensitization
- Molar pregnancy

Transfer criteria:

If out-of-hospital birth is planned, certain intrapartum and postpartum complications may necessitate transfer to a hospital to meet coverage criteria. For these indications, an attempt should be made to transfer the mother and/or her newborn; however, imminent fetal delivery may delay or preclude actual transfer prior to birth.

*Maternal*

- Temperature  $\geq 38.0$  C
- Maternal infection requiring hospital treatment (e.g. endometritis or wound infection)
- Hemorrhage (hypovolemia, shock, need for transfusion)
- Retained placenta > 60 minutes
- Laceration requiring hospital repair (e.g., extensive vaginal, cervical or third- or fourth-degree trauma)
- Enlarging hematoma
- Bladder or rectal dysfunction

*Fetal and uterine*

- Repetitive or persistent abnormal fetal heart rate pattern
- Thick meconium staining of amniotic fluid

**GUIDELINE NOTE 153, PLANNED OUT-OF-HOSPITAL BIRTH (CONT'D)**

- Prolapsed umbilical cord
- Failure to progress (as defined by the American Congress of Obstetricians and Gynecologists, March 2014, found at <http://www.acog.org/Resources-And-Publications/Obstetric-Care-Consensus-Series/Safe-Prevention-of-the-Primary-Cesarean-Delivery>)/failure of head to engage in active labor
- Chorioamnionitis or other serious infection (including toxoplasmosis, rubella, CMV, HIV, etc.)
- Uterine rupture, inversion or prolapse

If the infant is delivered out-of-hospital, the following complications require transfer to a hospital for the out-of-hospital birth to meet coverage criteria:

- Low Apgar score (< 5 at 5 minutes, < 7 at 10 minutes)
- Weight less than 5th percentile for gestational age
- Unexpected significant or life-threatening congenital anomalies
- Respiratory or cardiac irregularities, cyanosis, pallor
- Temperature instability, fever, suspected infection or dehydration
- Hyperglycemia/hypoglycemia unresponsive to treatment
- Hypotonia, tremors, seizures, hyperirritability
- Excessive bruising, enlarging cephalohematoma, significant birth trauma
- Vomiting/diarrhea

Consultation criteria:

Certain high risk conditions require consultation (by a provider of maternity care who is credentialed to admit and manage pregnancies in a hospital) for coverage of a planned out-of-hospital birth to be recommended. These complications include (but are not limited to) patients with:

*Complications in a previous pregnancy:*

**Maternal**

- More than three first trimester spontaneous abortions, or more than one second trimester spontaneous abortion
- More than one preterm birth, or preterm birth less than 34 weeks 0 days in most recent pregnancy
- Pre-eclampsia, not requiring preterm birth
- Cervical insufficiency/prior cerclage
- Third degree laceration; fourth-degree laceration with satisfactory functional recovery
- Life-threatening congenital anomalies (unless fatal anomalies with nonresuscitation planned)
- Postpartum hemorrhage requiring additional pharmacologic treatment or blood transfusion
- Retained placenta requiring manual removal

**Fetal**

- Child with congenital and/or hereditary disorder
- Baby > 4.5 kg or 9 lbs 14 oz
- Shoulder dystocia, with or without fetal clavicular fracture
- Unexplained stillbirth/neonatal death or previous death unrelated to intrapartum difficulty
- Unresolved intrauterine growth restriction (IUGR) or small for gestational age (defined as fetal or birth weight less than fifth percentile using ethnically-appropriate growth tables)
- Blood group incompatibility, and/or Rh sensitization

*Complications of current pregnancy:*

**Maternal**

- Inadequate prenatal care (defined as less than five prenatal visits or care began in the third trimester)
- Body mass index at first prenatal visit of greater than 35 kg/m<sup>2</sup>
- History of maternal seizure disorder (excluding eclampsia)
- Gestational diabetes, diet-controlled
- Maternal mental illness with suspicion for psychosis or potential harm to self or infant under outpatient psychiatric care
- Maternal anemia with hemoglobin < 10.5 g/dL, unresponsive to treatment
- Third-degree laceration not requiring hospital repair
- Laparotomy during pregnancy

**Fetal**

- Fetal macrosomia (estimated weight >4.5 kg or 9 lbs 14 oz)
- Confirmed intrauterine death
- Family history of genetic/heritable disorders that would impact labor, delivery or newborn care

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 154, EAR DRUM REPAIR**

*Lines 311,444,473*

Repair of open wounds or perforations of the ear drum (codes included on these lines from ICD-10-CM H72, S09.2) are only included on Lines 311 and 444 when there is documented conductive hearing loss greater than or equal to 25dB persistent for more than three months. Otherwise, such repairs are included on Line 473 CHRONIC OTITIS MEDIA; OPEN WOUND OF EAR DRUM.

**GUIDELINE NOTE 155, ELECTRIC TUMOR TREATMENT FIELDS FOR GLIOBLASTOMA**

*Line 294*

Electric tumor treatment fields (codes HCPCS A4555 and E0766) are included on this line only when

- A) Used for the initial treatment of supratentorial glioblastoma
- B) Used in combination with temozolomide

Electric tumor treatment fields are not included on this line for recurrent glioblastoma or any other indication.

**GUIDELINE NOTE 156, ENCOUNTER FOR DESENSITIZATION TO ALLERGENS**

*Lines 9,103,124,223,313,530,531,550,559,566*

ICD-10-CM Z51.6 (Encounter for desensitization to allergens) is only included on these lines when used to treat a diagnosis appearing on a line above the current funding line (i.e. Lines 9, 103, 124, 223 and 313).

**GUIDELINE NOTE 157, WIGS**

*Line 422*

Wigs (HCPCS A9282) are covered only for hair loss due to chemotherapy or radiation therapy.

**GUIDELINE NOTE 158, HALLUX RIGIDUS**

*Lines 356,540*

Surgical treatment of hallux rigidus is included on Line 356 only for

- Stage 3 and 4 disease when paired with arthroplasty (CPT 28750), the Keller procedure (CPT 28292), or cheilectomy with implant (CPT 28291)
- Stage 2 disease when paired with cheilectomy (CPT 28289) and there is documentation that conservative therapy (e.g. injection, physical therapy, orthotics) has been tried and failed to adequately control symptoms.

Otherwise surgical treatment of this diagnosis is included on Line 540.

**GUIDELINE NOTE 159, SMOKING AND SURGICAL TREATMENT OF ERECTILE DYSFUNCTION**

*Line 521*

Surgical treatment of erectile dysfunction is only included on this line when patients are non-smoking and abstinent from all nicotine products for 6 months prior to surgery, as shown by negative cotinine levels at least 6 months apart, with the second test within 1 month of the surgery date.

**GUIDELINE NOTE 160, CONGENITAL MUSCULAR TORTICOLLIS**

*Line 401*

Congenital muscular torticollis (ICD-10-CM Q68.0 Congenital deformity of sternocleidomastoid muscle) is paired with physical therapy on this line only in the following circumstances:

- 1) The patient is a child aged 2 years or younger
- 2) For patients with deficits of passive rotation of the neck of < 10 degrees, one therapy visit is included for instructing caregivers on home treatment.
- 3) For patients with deficits of passive rotation of the neck of > 10 degree or with deficits of passive rotation of the neck of < 10 degrees who have had no improvement after 4 weeks of home treatment, physical therapy is included on this line according to Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES.

**GUIDELINE NOTE 161, SACROILIAC ANESTHETIC INJECTIONS AND SACROILIAC JOINT FUSION**

*Line 527*

Sacroiliac joint (SIJ) injection (CPT 20610 and 27096, and HCPCS G0260) is included on this line for diagnostic sacroiliac injections with anesthetic only, but not for therapeutic injections or corticosteroid injections. Injections are only covered for patients for whom SIJ fusion surgery is being considered.

SIJ fusion (CPT 27279) is included on this line for patients who have all of the following:

- A) Baseline score of at least 30% on the Oswestry Disability Index (ODI)

**GUIDELINE NOTE 161, SACROILIAC ANESTHETIC INJECTIONS AND SACROILIAC JOINT FUSION (CONT'D)**

- B) Undergone and failed a minimum six months of intensive non-operative treatment that must include non-opioid medication optimization and active therapy. Active therapy is defined as activity modification, chiropractic/osteopathic manipulative therapy, bracing, and/or active therapeutic exercise targeted at the lumbar spine, pelvis, SIJ and hip including a home exercise program. Failure of conservative therapy is defined as less than a 50% improvement on the ODI.
- C) Typically unilateral pain that is caudal to the lumbar spine (L5 vertebrae), localized over the posterior SIJ, and consistent with SIJ pain.
- D) Thorough physical examination demonstrating localized tenderness with palpation over the sacral sulcus (Fortin's point, i.e. at the insertion of the long dorsal ligament inferior to the posterior superior iliac spine or PSIS) in the absence of tenderness of similar severity elsewhere (e.g. greater trochanter, lumbar spine, coccyx) and that other obvious sources for their pain do not exist.
- E) Positive response to at least three of six provocative tests (e.g. thigh thrust test, compression test, Gaenslen's test, distraction test, Patrick's sign, posterior provocation test).
- F) Absence of generalized pain behavior (e.g. somatoform disorder) and generalized pain disorders (e.g. fibromyalgia).
- G) Diagnostic imaging studies that include ALL of the following:
  - 1) Imaging (plain radiographs and a CT or MRI) of the SIJ that excludes the presence of destructive lesions (e.g. tumor, infection), fracture, traumatic sacroiliac joint instability, or inflammatory arthropathy that would not be properly addressed by percutaneous SIJ fusion
  - 2) Imaging of the pelvis (AP plain radiograph) to rule out concomitant hip pathology
  - 3) Imaging of the lumbar spine (CT or MRI) to rule out neural compression or other degenerative condition that can be causing low back or buttock pain
  - 4) Imaging of the SIJ that indicates evidence of injury and/or degeneration
- H) At least 75 percent reduction of pain for the expected duration of two anesthetics (on separate visits each with a different duration of action), and the ability to perform previously painful maneuvers, following an image-guided, contrast-enhanced intra-articular SIJ injection.

**GUIDELINE NOTE 162, LONG-ACTING REVERSIBLE CONTRACEPTIVE (LARC) PLACEMENT**

*Line 6*

Long-acting reversible contraceptives (implant or intrauterine device) are included on Line 6 in all settings, including (but not limited to) immediately postpartum and postabortion.

The development of this guideline note was informed by a HERC [coverage guidance](http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

**GUIDELINE NOTE 163, SKIN SUBSTITUTES FOR CHRONIC SKIN ULCERS**

*Line 379*

Skin substitutes for chronic venous leg ulcers and chronic diabetic foot ulcers are included on this line when all of the following criteria are met:

- 1) FDA indications and contraindications are followed, if applicable
- 2) Wound has adequate arterial flow (ABI > 0.7), no ongoing infection and a moist wound healing environment
- 3) For patients with diabetes, Hba1c level is < 12
- 4) Prior appropriate wound care therapy (including but not limited to appropriate offloading, multilayer compression dressings and smoking cessation counseling) has failed to result in significant improvement (defined as at least a 50 percent reduction in ulcer surface area) of the wound over at least 30 days
- 5) Ongoing coverage requires significant improvement of the ulcer with skin substitute application over the preceding 6 week time period
- 6) Patients is able to adhere to the treatment plan
- 7) The use of skin substitutes is not included on this line for chronic skin ulcers other than venous leg ulcers and diabetic foot ulcers (e.g., pressure ulcers)

Note: There is no evidence supporting superiority of one skin substitute versus another and new studies are constantly being published. Decisions for specific products could be made based on at least one supportive randomized controlled trial, and those that involve fewer applications, and are lower cost.

**GUIDELINE NOTE 164, PERCUTANEOUS REPAIR OF PARAVALVULAR LEAKS**

*Line 285*

Percutaneous transcatheter closure of paravalvular leak (CPT 93590-93592) is included on this line only for patients with

- 1) prosthetic heart valves with paravalvular leak AND
- 2) intractable hemolysis or NYHA class III/IV heart failure AND
- 3) who are at high risk for surgery and have anatomic features suitable for catheter-based therapy AND
- 4) when performed in centers with expertise in the procedure.

**GUIDELINE NOTE 165, FECAL MICROBIOTA TRANSPLANT**

*Line 146*

Fecal microbiota transplant (FMT); (CPT 44705, HCPCS G0455) is included on this line for treatment of recurrent C difficile infection only.

**GUIDELINE NOTE 166, BREAST REDUCTION SURGERY FOR MACROMASTIA**

*Line 558*

Breast reduction surgery for macromastia is not covered as a treatment for neck or back pain resulting from the macromastia due to lack of high quality evidence of effectiveness.

**GUIDELINE NOTE 167, CHOLECYSTECTOMY FOR CHOLECYSTITIS AND BILIARY COLIC**

*Lines 55,639*

Cholecystectomy for cholecystitis and biliary colic are including on Line 55 when meeting the following criteria:

- A) For cholecystitis, with either:
    - 1) The presence of right upper quadrant abdominal pain, mass, tenderness or a positive Murphy's sign, AND
    - 2) Evidence of inflammation (e.g. fever, elevated white blood cell count, elevated C reactive protein) OR
    - 3) Ultrasound findings characteristic of acute cholecystitis or non-visualization of the gall bladder on oral cholecystogram or HIDA scan, or gallbladder ejection fraction of < 35%.
  - B) For biliary colic (i.e. documented clinical encounter for right upper quadrant or epigastric pain with gallstones seen on imaging during each episode) without evidence of cholecystitis or other complications is included on Line 55 only when
    - 1) Recurrent (i.e. 2 or more episodes in a one year period) OR
    - 2) A single episode in a patient at high risk for complications with emergent cholecystitis (e.g. immunocompromised patients, morbidly obese patients, diabetic patients) OR
    - 3) When any of the following are present: elevated pancreatic enzymes, elevated liver enzymes or dilated common bile duct on ultrasound.
- Otherwise, biliary colic is included on Line 639.

**GUIDELINE NOTE 168, INTRASTROMAL CORNEAL RING SEGMENTS**

*Line 310*

Insertion of intrastromal corneal ring segments (CPT 65785) is included on this line only for reduction or elimination of myopia or astigmatism in adults age 19 and older with keratoconus who are no longer able to achieve adequate functional vision to perform ADLs with best correction using contact lenses or spectacles, who have a corneal thickness of 450 microns or greater at proposed incision site, and for whom corneal transplant is the only remaining option to improve their functional vision.

**GUIDELINE NOTE 169, ORTHODONTICS AND CRANIOFACIAL SURGERY FOR CRANIOFACIAL ANOMALIES**

*Line 257*

Orthodontics and craniofacial surgery are included on this line only for pairing with craniofacial anomaly diagnoses when there is significant malocclusion expected to result in difficulty with mastication, speech, or other oral function. Advanced dental imaging is included on this line only when required for surgical planning for repair of craniofacial anomalies.

**GUIDELINE NOTE 170, INTRATHECAL OR EPIDURAL DRUG INFUSION**

*Lines 71,285,292,489*

Implantation, revision and replacement of devices for intrathecal or epidural drug infusion systems is only included on these lines when the patient meets the criteria for at least one of the categories (A or B) below:

- A) Placed for administration of baclofen for spasticity where all of the following (1-3) occur:
  - 1) The patient has had an adequate trial of non-invasive methods of spasticity control and not had adequate control of spasticity or had intolerable side effects with these methods.
  - 2) The spasticity is causing difficulties with at least one of the following (a, b or c):
    - a) Posture or function
    - b) Balance or locomotion
    - c) Self-care (or ease of care by parents or caregivers)
  - 3) The patient has a favorable response to a trial intrathecal dosage of the anti-spasmodic drug prior to pump implantation.
- B) Palliation for severe, intractable pain due to life-limiting active cancer which
  - 1) Has not been responsive to non-invasive systemic pain control strategies or had intolerable side effects from such strategies, AND
  - 2) Where the patient has a favorable response to a trial of an intrathecal dose of the analgesic drug prior to pump implantation

Intrathecal or epidural drug infusion pump insertion, revision, and replacement are included on Line 660 for use with chronic non-malignant pain and all other indications not listed above. See Guideline Note 173 INTERVENTIONS THAT ARE UNPROVEN, HAVE

**GUIDELINE NOTE 170, INTRATHECAL OR EPIDURAL DRUG INFUSION (CONT'D)**

NO CLINICALLY IMPORTANT BENEFIT OR HAVE HARMS THAT OUTWEIGH BENEFITS FOR CERTAIN CONDITIONS. Removal of pumps placed for such indications is included on Line 285.

Maintenance (i.e. reprogramming, medication refill) of epidural or intrathecal medication infusion pumps for any condition is only included on these lines for patients who

- A) have no significant complications with the current medication regimen or pump delivery system AND
- B) are continuing to receive adequate benefit from the pump-delivered medication.

Maintenance (but not replacement) of these infusion systems may be paired with ICD-10-CM Z45.49 (Encounter for adjustment and management of other implanted nervous system device).

**GUIDELINE NOTE 171, LATTICE DEGENERATION, ASYMPTOMATIC RETINAL BREAKS AND ROUND HOLES**

*Lines 374,652*

Lattice degeneration is included on Line 374 only for pairing with ophthalmologic visits and dilated eye exams, and only for patients at high risk of retinal detachment:

- A) Patients under the age of 65 years with round holes and myopic vision, OR
- B) Patients with a history of retinal detachment in the other eye OR,
- C) Patients with biologic family member with history of retinal tear or retinal detachment

Otherwise, lattice degeneration is included on Line 652.

Retinal breaks and round holes are only included for pairing with treatment (other than ophthalmologic visits and dilated eye exams) on Line 374 when they are symptomatic, the result of trauma, or are horseshoe breaks. Otherwise, these diagnoses are included on Line 652.

**GUIDELINE NOTE 172, INTERVENTIONS WITH MARGINAL CLINICAL BENEFIT OR LOW COST-EFFECTIVENESS FOR CERTAIN CONDITIONS**

*Line 500*

The following interventions are prioritized on Line 500 CONDITIONS FOR WHICH INTERVENTIONS RESULT IN MARGINAL CLINICAL BENEFIT OR LOW COST-EFFECTIVENESS:

Procedure Code	Intervention Description	Rationale	Last Review
S2300	Arthroscopy, shoulder, surgical; with thermally-induced capsulorrhaphy	More effective treatments are available	<a href="#">September, 2017</a>
11981 G0516, G0518	Implantable buprenorphine for opioid use disorder for patients who are clinically stable on 8 mg daily or less of buprenorphine or equivalent for at least 6 months	Not cost effective compared to equally efficacious alternative formulations	November, 2017
61630	Balloon angioplasty, intracranial (eg, atherosclerotic stenosis), percutaneous	Similar or worse outcomes than standard therapies	<a href="#">March 2016</a>
64566	Posterior tibial neurostimulation	Minimally effective, no evidence of long-term effectiveness	<a href="#">December, 2010</a>
69710  HCPCS L8690- L8693	Implantation or replacement of electromagnetic bone conduction hearing device in temporal bone  Auditory osseointegrated device	Less effective than other therapies	<a href="#">June, 2014, Aug. 2015</a>
74263, 81528, 81327	Screening CT Colonography, FIT-DNA (Cologuard), mSEPT9, Chromoscopy	Insufficient evidence for use in population screening	<a href="#">September, 2017</a>
94669	Mechanical chest wall oscillation	More costly than equally effective therapies	<a href="#">October, 2016</a>
95250-95251	Retrospective (professional) continuous glucose monitoring	Limited evidence of clinical utility	<a href="#">August, 2017</a>
99174, 99177	Photoscreening	More costly than equally effective methods of screening	<a href="#">November, 2015</a>

**GUIDELINE NOTE 173, INTERVENTIONS THAT ARE UNPROVEN, HAVE NO CLINICALLY IMPORTANT BENEFIT OR HAVE HARMS THAT OUTWEIGH BENEFITS FOR CERTAIN CONDITIONS**

*Line 660*

The following Interventions are prioritized on Line 660 CONDITIONS FOR WHICH CERTAIN INTERVENTIONS ARE UNPROVEN, HAVE NO CLINICALLY IMPORTANT BENEFIT OR HAVE HARMS THAT OUTWEIGH BENEFITS:

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
D0422	Collection and preparation of genetic sample material for laboratory analysis and report	Insufficient evidence of effectiveness	<a href="#">October, 2015</a>
D0423	Genetic test for susceptibility to diseases – specimen analysis		
D9932-D9935	Cleaning and inspection of removable complete or partial denture, maxillary or mandibular	Insufficient evidence of effectiveness	<a href="#">October, 2015</a>
G0106, G0120, G0122	Barium enema as a colorectal cancer screening modality	Not indicated as a CRC screening modality	<a href="#">November, 2017</a>
S9357	Enzyme replacement therapy (e.g. idursulfase and similar medications) for all inborn error of metabolism conditions except infantile Pompe's disease	No clinically important benefit	<a href="#">August, 2012</a>
11981 G0516, G0518	Implantable buprenorphine for opioid use disorder for patients other than those who are clinically stable on 8 mg daily or less of buprenorphine or equivalent for at least 6 months	Unproven treatment	November, 2017
15777	Acellular dermal matrix for soft tissue reinforcement (eg, breast, trunk)	Greater harms than other effective therapies	<a href="#">March, 2015</a>
19294	Intraoperative radiation therapy (IORT) concurrent with partial mastectomy	Unproven treatment	<a href="#">November, 2017</a>
20696-20697	Application of multiplane (pins or wires in more than 1 plane), unilateral, external fixation with stereotactic computer-assisted adjustment (eg, spatial frame)		
20939	Bone marrow aspiration for bone grafting, spine surgery	Unproven treatment	<a href="#">November, 2017</a>
20979	Low intensity ultrasound stimulation to aid bone healing, noninvasive (nonoperative)		
20982	Radiofrequency ablation therapy for reduction or eradication of 1 or more bone tumors	No evidence of effectiveness	2004
20983	Cryotherapy ablation therapy for reduction or eradication of 1 or more bone tumors	No evidence of effectiveness	November, 2014
21685	Hyoid myotomy and suspension		
22867-22870	Insertion of interlaminar/ interspinous process stabilization/ distraction device, without fusion, including image guidance when performed, with open decompression, lumbar	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
27080	Coccygectomy, primary		
27418	Anterior tibial tubercleplasty (eg, Maquet type procedure)	Harms outweigh benefits, more efficacious procedures exist	May, 2011
28890	Extracorporeal shock wave, high energy involving the plantar fascia		
29866-29867	Arthroscopy, knee, surgical; osteochondral autograft(s)/allograft(s) (eg, mosaicplasty)		
29868	Arthroscopy, knee, surgical; meniscal transplantation		
31627	Computer assisted bronchoscopy	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
31647-31649, 31651	Bronchial valve insertion/removal/replacement	Insufficient evidence of effectiveness	<a href="#">December, 2012</a>
31660-31661	Bronchial thermoplasty	Insufficient evidence of effectiveness	<a href="#">January, 2014</a>
32998	Radiofrequency ablation therapy for reduction or eradication of 1 or more pulmonary tumor(s)		
33140-33141	Transmyocardial laser revascularization, by thoracotomy		
33340	Percutaneous transcatheter closure of the left atrial appendage with endocardial implant	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
33548	Surgical ventricular restoration procedure, includes prosthetic patch, when performed (eg, ventricular remodeling, SVR, SAVER, Dor procedures)		

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
33927-33929	Total artificial heart	Unproven treatment	<a href="#">November, 2017</a>
36455	Exchange transfusion, blood; other than newborn		
36456	Partial exchange transfusion, blood, plasma or crystalloid necessitating the skill of a physician or other qualified health care professional, newborn	No evidence of effectiveness, evidence of possible harm	<a href="#">November, 2016</a>
36482-36483	Endovenous ablation therapy of incompetent vein, extremity, by transcatheter delivery of a chemical adhesive (eg, cyanoacrylate)	Unproven treatment	<a href="#">November, 2017</a>
41512	Tongue base suspension	No clinically important benefit	<a href="#">January, 2014</a>
41530	Submucosal ablation of the tongue base, radiofrequency		
41821	Operculectomy, excision pericoronal tissue		
43206	Esophagoscopy, flexible, transoral; with optical endomicroscopy	No evidence of effectiveness	December, 2012
43252, 88375	Optical endomicroscopy	Insufficient evidence of effectiveness	<a href="#">December, 2012</a>
43257	Esophagogastroduodenoscopy, flexible, transoral; with delivery of thermal energy to the muscle of lower esophageal sphincter and/or gastric cardia, for treatment of gastroesophageal reflux disease	No evidence of effectiveness	January, 2014
43284	Laparoscopy, surgical, esophageal sphincter augmentation procedure, placement of sphincter augmentation device (ie, magnetic band)	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
43647-43648 43881-43882	Laparoscopy, surgical; implantation or replacement or revision of gastric neurostimulator electrodes, antrum		
43770, 43842-43845, 43886-43888	Gastric restrictive procedures (gastric band, other)	No evidence of effectiveness	October, 2016
45391-45392	Colonoscopy, flexible; with endoscopic ultrasound examination		
46760-46762	Sphincteroplasty, anal, for incontinence, adult; muscle transplant/implantation artificial sphincter	No evidence of effectiveness	May, 2013
47383	Ablation, 1 or more liver tumor(s), percutaneous, cryoablation	No evidence of effectiveness for both hepatocellular carcinoma and metastatic disease	November, 2013
50380	Renal autotransplantation, reimplantation of kidney		
50592	Radiofrequency ablation, 1 or more renal tumor(s)		
50705	Ureteral embolization or occlusion	Insufficient evidence of effectiveness	<a href="#">November, 2015</a>
52441-52442	Cystourethroscopy, with insertion of permanent adjustable transprostatic implant	No evidence of effectiveness	March, 2015 <a href="#">Coverage Guidance</a>
52647	Laser coagulation of prostate	No evidence of effectiveness	March, 2015 <a href="#">Coverage Guidance</a>
53855	Temporary prostatic stents	Insufficient evidence of effectiveness	<a href="#">October, 2015</a>
53860	Transurethral radiofrequency micro-remodeling of the bladder neck and urethra for stress incontinence	Insufficient evidence of effectiveness	<a href="#">December, 2010</a>
55300	Vasotomy for vasograms, seminal vesiculograms, or epididymogram		
55873	Cryosurgical ablation of the prostate		
55874	Absorbable perirectal spacer for use during prostate cancer radiation therapy	Unproven treatment	<a href="#">November, 2017</a>
58674	Laparoscopy, surgical, ablation of uterine fibroid(s)	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
61635	Transcatheter placement of intravascular stent(s), intracranial (eg, atherosclerotic stenosis), including balloon angioplasty, if performed	Results in significantly worse outcomes than medical management	<a href="#">March 2016</a>
61640-61642	Balloon dilation of intracranial vasospasm, percutaneous.	Evidence of harm	<a href="#">March, 2016</a>
61645	Percutaneous arterial transluminal mechanical thrombectomy and/or infusion for thrombolysis, intracranial	No evidence of effectiveness	November, 2015
61650-61651	Endovascular intracranial prolonged administration of pharmacologic agent(s) other than for thrombolysis, arterial	No evidence of effectiveness	November, 2015
62263	Percutaneous lysis of epidural adhesions using solution injection (eg, hypertonic saline, enzyme) or mechanical means		
62290-62292 72285, 72295	Discography		
62380	Endoscopic decompression of spinal cord, nerve root(s), including laminotomy, partial facetectomy, foraminotomy, discectomy and/or excision of herniated intervertebral disc	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
64479-64480	Transforaminal epidural steroid injections, cervical and thoracic spine	Insufficient evidence of benefit	<a href="#">March, 2015</a>  <a href="#">Coverage Guidance Blog</a>
64490-64492	Facet joint injections cervical and thoracic	Insufficient evidence of benefit	<a href="#">March, 2015</a>  <a href="#">Coverage Guidance Blog</a>
64550, 97014, 97032, 0278T, E0720, E0730, G0283	Transcutaneous electrical nerve stimulation (TENS); Scrambler therapy; Cranial electrical stimulation; all similar transcutaneous electrical neurostimulation therapies	No clinically important benefit (CES) or insufficient evidence of effectiveness (all other) for chronic pain; insufficient evidence of effectiveness for all other indications	<a href="#">September, 2017</a>
64617	Chemodenervation of muscle(s); larynx	No evidence of effectiveness	January, 2014
64633-64634	Radiofrequency ablation of the cervical and thoracic spine	Insufficient evidence of benefit	<a href="#">March, 2015</a>  <a href="#">Coverage Guidance Blog</a>
64635-64636	Radiofrequency ablation of the lumbar and sacral spine	Insufficient evidence of benefit	<a href="#">November, 2014</a>  <a href="#">Coverage Guidance Blog</a>
64912-64913	Nerve repair; with nerve allograft	Unproven treatment	<a href="#">November, 2017</a>
66174-66175	Transluminal dilation of aqueous outflow canal	Insufficient evidence of effectiveness	<a href="#">December, 2010</a>
69720-69725	Decompression facial nerve		
69740-69745	Suture facial nerve		
69955	Total facial nerve decompression and/or repair		
70554-70555	Functional MRI		
74261-74262	Computed tomographic (CT) colonography		
75571	CT coronary calcium scoring	Insufficient evidence of benefit, unclear harms of radiation exposure	<a href="#">August 2013</a>  <a href="#">Coverage Guidance Blog</a>
75572	Computed tomography, heart, with contrast material, for evaluation of cardiac structure and morphology	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
75574	Computed tomography, heart	Insufficient evidence of benefit, unclear harms of radiation exposure	<a href="#">August, 2013</a>  <a href="#">Coverage Guidance Blog</a>
76376-76377	3D rendering		
77061-77063	Digital breast tomosynthesis	No evidence of effectiveness	November, 2014

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
77084	Magnetic resonance (eg, proton) imaging, bone marrow blood supply		
77086	Vertebral fracture assessment using DXA	Insufficient evidence of effectiveness	<a href="#">October, 2015</a>
77767	Remote afterloading high dose rate radionuclide skin surface brachytherapy, includes basic dosimetry	Insufficient evidence of effectiveness	<a href="#">October and November 2015</a>
77768	Skin surface brachytherapy	No evidence of effectiveness	November, 2015
78265-78266	Gastric emptying imaging study	No evidence of effectiveness	November, 2015
78459	Myocardial imaging, positron emission tomography (PET), metabolic evaluation	Insufficient evidence of benefit, unclear harms of radiation exposure	<a href="#">January, 2015</a> <a href="#">Coverage Guidance Blog</a>
78491-78492	Myocardial imaging, positron emission tomography (PET), perfusion	Insufficient evidence of benefit, unclear harms of radiation exposure	<a href="#">January, 2015</a> <a href="#">Coverage Guidance Blog</a>
81225-81227, 81230-81231	Cytochrome P450 gene analysis	Insufficient evidence of effectiveness	December, 2011 <a href="#">November, 2017</a>
81232, 81246	5-fluorouracil/5-FU and capecitabine drug metabolism	Insufficient evidence of effectiveness	<a href="#">November, 2017</a>
81283	IFNL3 (interferon, lambda 3) (eg, drug response), gene analysis, rs12979860 variant	Insufficient evidence of effectiveness	<a href="#">November, 2017</a>
81287	MGMT (O-6-methylguanine-DNA methyltransferase) (eg, glioblastoma multiforme), methylation analysis	Insufficient evidence of effectiveness	January, 2014
81291	MTHFR (5,10-methylenetetrahydrofolate reductase) gene analysis, common variants	Insufficient evidence of effectiveness	December, 2011
81328	SLCO1B1 (solute carrier organic anion transporter family, member 1B1) gene analysis, common variant(s)	Insufficient evidence of effectiveness	<a href="#">November, 2017</a>
81330	SMPD1(sphingomyelin phosphodiesterase 1, acid lysosomal) gene analysis, common variants	Insufficient evidence of effectiveness	December, 2011
81335	TPMT (thiopurine S-methyltransferase) (eg, drug metabolism), gene analysis	Insufficient evidence of effectiveness	<a href="#">November, 2017</a>
81350	UGT1A1 (UDP glucuronosyl-transferase 1 family, polypeptide A1) (eg, irinotecan metabolism), gene analysis, common variants	Insufficient evidence of effectiveness	December, 2011
81355	VKORC1 (vitamin K epoxide reductase complex, subunit 1) (eg, warfarin metabolism), gene analysis, common variants	Insufficient evidence of effectiveness	December, 2011
81417	Re-evaluation of whole exome sequencing	Insufficient evidence of effectiveness	December, 2011
81422	Fetal chromosomal microdeletion(s) genomic sequence analysis (eg, DiGeorge syndrome, Cri-du-chat syndrome), circulating cell-free fetal DNA in maternal blood	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
81425-81427	Genome sequence analysis	Insufficient evidence of effectiveness	November, 2014
81470, 81471	X-linked intellectual disability (XLID) genomic sequence panels	Insufficient evidence of effectiveness	November, 2014
81490	Autoimmune (rheumatoid arthritis), analysis of 12 biomarkers using immunoassays, utilizing serum, prognostic algorithm	No evidence of effectiveness	November, 2015
81493	Coronary artery disease, mRNA, gene expression profiling	Insufficient evidence of effectiveness	<a href="#">November, 2015</a>
81500	Oncology (ovarian), biochemical assays of two proteins (CA-125 and HE4), utilizing	No evidence of effectiveness	December, 2012

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
	serum, with menopausal status, algorithm reported as a risk score		
81503	Oncology (ovarian), biochemical assays of five proteins (CA-125, apolipoprotein A1, beta-2 microglobulin, transferrin, and pre-albumin), utilizing serum, algorithm reported as a risk score	No evidence of effectiveness	December, 2012
81504	Biomarker tests for tumor tissue: <ul style="list-style-type: none"> <li>• Mammaprint, Mammostrat and ImmunoHistoChemistry 4 (IHC4) for breast cancer</li> <li>• Microsatellite instability (MSI) for colorectal cancer</li> <li>• Urovysion for bladder cancer</li> <li>• Prolaris for prostate cancer</li> <li>• Multiple molecular testing to select targeted cancer therapy</li> </ul>	Insufficient evidence of effectiveness. More costly than equally effective therapies for this condition	<a href="#">August, 2015</a> <a href="#">Coverage Guidance Blog</a>
81506	Endocrinology (type 2 diabetes), biochemical assays of seven analytes (glucose, HbA1c, insulin, hs-CRP, adiponectin, ferritin, interleukin 2-receptor alpha), utilizing serum or plasma, algorithm reporting a risk score	No evidence of effectiveness	December, 2012
81521	Oncology (breast), mRNA, microarray gene expression profiling of 70 content genes and 465 housekeeping genes	Unproven intervention	August, 2015
81535-81536	Oncology (gynecologic), live tumor cell culture and chemotherapeutic response by DAPI stain and morphology, predictive algorithm reported as a drug response score	No evidence of effectiveness	November, 2015
81538	Oncology (lung), mass spectrometric 8-protein signature, including amyloid A, utilizing serum, prognostic and predictive algorithm reported as good versus poor overall survival	No evidence of effectiveness	November, 2015
81539	Oncology (high-grade prostate cancer), biochemical assay of four proteins (Total PSA, Free PSA, Intact PSA, and human kallikrein-2[hk2]), utilizing plasma or serum, prognostic algorithm reported as a probability score	Insufficient evidence of effectiveness	<a href="#">November, 2016</a>
81540	Oncology (tumor of unknown origin), mRNA, gene expression profiling by real-time RT-PCR of 92 genes (87 content and 5 housekeeping) to classify tumor into main cancer type and subtype, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported	No evidence of effectiveness	November, 2015
81541	Oncology (prostate), mRNA gene expression profiling by real-time RT-PCR of 46 genes (31 content and 15 housekeeping)	Unproven intervention	August, 2015
81545	Oncology (thyroid), gene expression analysis of 142 genes, utilizing fine needle aspirate, algorithm reported as a categorical result	No evidence of effectiveness	November, 2015
81551	Oncology (prostate), promoter methylation profiling by real-time PCR of 3 genes (GSTP1, APC, RASSF1)	Unproven intervention	<a href="#">November, 2017</a>
82107	Alpha-fetoprotein (AFP); AFP-L3 fraction isoform and total AFP		
82610	Cystatin		
82757	Fructose, semen		
82777	Galectin-3	No evidence of effectiveness	November, 2015
83006	Growth stimulation expressed gene 2 (ST2, Interleukin 1 receptor like-1)	No evidence of effectiveness	November, 2014
83037	Hemoglobin; glycosylated (A1C) by device cleared by FDA for home us3		

GUIDELINE NOTES FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)

Procedure Code	Intervention Description	Rationale	Last Review
83631	Lactoferrin, fecal; quantitative		
83695	Lipoprotein (a)	No evidence of effectiveness	January, 2014
83698	Lipoprotein-associated phospholipase A2 (Lp-PLA2)		
83700-87004	Lipoprotein, blood		
83861	Tear osmolarity		
83951	Oncoprotein; des-gamma-carboxy-prothrombin (DCP)		
83987	pH; exhaled breath condensate	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
83993	Calprotectin, fecal		
84145	Procalcitonin (PCT)	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
84431	Thromboxane metabolite(s)	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
86001	Allergen specific IgG testing	No clinically important benefit	<a href="#">November, 2017</a>
86005	Allergen specific IgE qualitative, multiallergen screen	No clinically important benefit	<a href="#">November, 2017</a>
86006	Allergen specific IgE, multiallergen screen	Harms outweigh benefits	<a href="#">November, 2017</a>
86152-86153	Cell enumeration using immunologic selection and identification in fluid specimen (eg, circulating tumor cells in blood)	No evidence of effectiveness	December, 2012
86305	Human epididymis protein 4 (HE4)	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
86356	Mononuclear cell antigen, quantitative (eg, flow cytometry)		
86386	Nuclear Matrix Protein 22 (NMP22), qualitative	No evidence of effectiveness	December, 2011
87905	Infectious agent enzymatic activity other than virus (eg, sialidase activity in vaginal fluid)		
88738	Hemoglobin (HGB), quantitative, transcutaneous	Insufficient evidence of effectiveness	<a href="#">December, 2009</a>
88740	Hemoglobin, quantitative, transcutaneous, per day; carboxyhemoglobin		
88741	Hemoglobin, quantitative, transcutaneous, per day; methemoglobin		
90845	Psychoanalysis	No longer utilized in clinical practice	
90869	Therapeutic repetitive transcranial magnetic stimulation (TMS) treatment	No evidence of effectiveness	December, 2012
90880	Hypnotherapy	No clinically important benefit	<a href="#">August, 2015</a>

**GUIDELINE NOTE 174, CRYOABLATION OF PULMONARY TUMORS***Line 263*

Cryoablation of pulmonary tumors is included on this line only for palliative treatment of an inoperable lung tumor with one of the following:

- A) Symptomatic proximal endobronchial obstruction, OR
- B) Presence of endobronchial lesion with associated lobar or greater parenchymal atelectasis, OR
- C) Hemoptysis from endobronchial location of the tumor.

**GUIDELINE NOTE 175, MEDICATION-ASSISTED TREATMENT OF OPIOID DEPENDENCE†***Lines 1,4*

In patients who meet criteria for opioid use disorder, programs that offer treatment of opioid use disorder must offer patients a variety of evidence-based interventions including behavioral interventions, social support, and Medication Assisted Treatment (MAT) and are individualized to the patient's needs. Intensive programs, such as inpatient residential treatment programs, are required to inform

**GUIDELINE NOTE 175, MEDICATION-ASSISTED TREATMENT OF OPIOID DEPENDENCE† (CONT'D)**

patients about MAT and to offer access to and support for MAT (including at least one form of opioid substitution therapy) if patients elect to receive it, to be included on this line.

MAT includes pharmacotherapy with opioid substitution therapy (methadone and buprenorphine) and opioid antagonists (naltrexone).

Detoxification alone is likely ineffective for producing long-term benefit and should be followed by a formal substance use disorder individualized treatment plan.

In pregnant women with opioid dependence, comprehensive treatment (including opioid substitution therapy) is included on this line.

†Implementation of Guideline Note 175 is being delayed by the Oregon Health Authority until July 1, 2018.

**GUIDELINE NOTE 176, OPPORTUNISTIC SALPINGECTOMY**

*Line 6*

Opportunistic salpingectomy during gynecologic procedures is included on Line 6, when it does not involve an increased payment (i.e., using a form of reference-based pricing) or require a change in the setting in which the procedure would be performed (e.g. necessitate a hospital setting instead of an ambulatory surgical center.)

The development of this guideline note was informed by a HERC [coverage guidance](#). See <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

# MULTISECTOR INTERVENTIONS

***Note: The multisector interventions described below are provided as an aid in population health management and do not constitute Oregon Health Plan benefits.***

*MULTISECTOR INTERVENTIONS  
FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)*

**MULTISECTOR INTERVENTIONS: TOBACCO PREVENTION AND CESSATION, INCLUDING DURING PREGNANCY**

Benefit coverage for smoking cessation on Line 5 and in Guideline Note 4 TOBACCO DEPENDENCE, INCLUDING DURING PREGNANCY is intended to be offered with minimal barriers, in order to encourage utilization. To further prevent tobacco use and help people quit, additional evidence-based policy and programmatic interventions from a population perspective are available here:

- Oregon Public Health Division's Health Promotion and Chronic Disease Prevention Section: Evidence-Based Strategies for Reducing Tobacco Use A Guide for CCOs  
[http://www.oregon.gov/oha/PH/PREVENTIONWELLNESS/TOBACCO/DOCUMENTS/evidence-based\\_strategies\\_reduce\\_tob\\_use\\_guide\\_cco.pdf](http://www.oregon.gov/oha/PH/PREVENTIONWELLNESS/TOBACCO/DOCUMENTS/evidence-based_strategies_reduce_tob_use_guide_cco.pdf)
- Community Preventive Services Task Force (supported by the CDC) - What Works: Tobacco Use  
<http://www.thecommunityguide.org/about/What-Works-Tobacco-factsheet-and-insert.pdf>

The Community Preventive Services Task Force identified the following evidence-based strategies:

TASK FORCE FINDINGS ON TOBACCO USE	
<p>The Community Preventive Services Task Force (Task Force) has released the following findings on what works in public health to prevent tobacco use. These findings are compiled in The Guide to Community Preventive Services (The Community Guide) and listed in the table below. Use the findings to identify strategies and interventions you could use for your community.</p> <p>Legend for Task Force Findings:  Recommended  Insufficient Evidence  Recommended Against (See reverse for detailed descriptions.)</p>	
Intervention	Task Force Finding
<b>Reducing Tobacco Use Initiation</b>	
Increasing the unit price of tobacco products	
Mass media campaigns when combined with other interventions	
Smoke-free policies	
<b>Increasing Tobacco Use Cessation</b>	
Increasing the unit price of tobacco products	
Mass media campaigns when combined with other interventions	
Mass-reach health communication interventions	
Mobile phone-based interventions	
Multicomponent interventions that include client telephone support	
Smoke-free policies	
Provider reminders when used alone	
Provider reminders with provider education	
Reducing client out-of-pocket costs for cessation therapies	
Internet-based interventions	
Mass media – cessation contests	
Mass media – cessation series	
Provider assessment and feedback	
Provider education when used alone	
Intervention	Task Force Finding
<b>Reducing Exposure to Environmental Tobacco Smoke</b>	
Smoke-free policies	
Community education to reduce exposure in the home	
<b>Restricting Minors' Access to Tobacco Products</b>	
Community mobilization with additional interventions	
Sales laws directed at retailers when used alone	
Active enforcement of sales laws directed at retailers when used alone	
Community education about youth's access to tobacco products when used alone	
Retailer education with reinforcement and information on health consequences when used alone	
Retailer education without reinforcement when used alone	
Laws directed at minors' purchase, possession, or use of tobacco products when used alone	
<b>Decreasing Tobacco Use Among Workers</b>	
Smoke-free policies	
Incentives and competitions to increase smoking cessation combined with additional interventions	
Incentives and competitions to increase smoking cessation when used alone	

Visit the "Tobacco Use" page of The Community Guide website at [www.thecommunityguide.org/tobacco](http://www.thecommunityguide.org/tobacco) to find summaries of Task Force findings and recommendations on tobacco use. Click on each topic area to find results from the systematic reviews, included studies, evidence gaps, and journal publications.

The Centers for Disease Control and Prevention provides administrative, research, and technical support for the Community Preventive Services Task Force.

To reduce the use of tobacco during pregnancy and improve associated outcomes, the evidence supports the following interventions:

- Financial incentives (incentives contingent upon laboratory tests confirming tobacco abstinence are the most effective)
- Smoke-free legislation
- Tobacco excise taxes

*MULTISECTOR INTERVENTIONS  
FOR THE JANUARY 1, 2018 PRIORITIZED LIST OF HEALTH SERVICES (REVISED)*

**MULTISECTOR INTERVENTIONS: PREVENTION OF EARLY CHILDHOOD CARIES**

Evidence supports:

- Community water fluoridation
- Fluoride varnish, including applied in a primary care setting
- Fluoride gel
- Oral fluoride supplementation
- Community-based programs that combine oral health education with supervised toothbrushing

Limited evidence supports:

- Motivational interviewing towards caregivers

Insufficient or conflicting evidence on:

- Anticipatory guidance/oral health education alone
- Encouragement of preventive dental visits
- Risk assessment
- Xylitol products
- Chlorhexidine
- Silver diamine fluoride
- School-based behavioral interventions
- Breastfeeding interventions

**MULTISECTOR INTERVENTIONS: PREVENTION AND TREATMENT OF OBESITY**

Limited evidence supports the following interventions:

- School and childcare settings
- School based interventions to reduce BMI (especially with physical activity focus)
- School nutrition policy and day care meal standards
- Family-based group education programs delivered in schools
- Obesity prevention interventions in childcare settings (nutrition education, healthy cooking classes for 2-6 year olds, physical activity and playful games)

Community level interventions

- Environmental interventions (social marketing, cafeteria signs, farmers markets, walking groups, etc)
- Introduction of light rail
- Community-based group health education and counseling interventions, workplace education interventions
- Workplace and college interventions to improve physical activity

Multiple settings:

- Interventions to reduce sedentary screen time (in some studies, also to increase physical activity and nutrition).
- Multicomponent individual mentored health promotion programs to prevent childhood obesity
- Parental support interventions for diet and physical activity (group education, mental health counseling)

Policy changes

- Sugar sweetened beverage taxes
- Elimination of tax subsidy for advertising unhealthy food to children

This Multisector Interventions statement is based on the work of the HERC Obesity Task Force and the full summary of the evidence report is available at <http://www.oregon.gov/oha/HPA/CSI-HERC/Pages/Evidence-based-Reports.aspx>.

## MEDICAL POLICY

### Tumor Treatment Field Therapy for Glioblastoma

#### GUIDELINES

**This policy does not certify benefits or authorization of benefits, which is designated by each individual policyholder contract. Paramount applies coding edits to all medical claims through coding logic software to evaluate the accuracy and adherence to accepted national standards. This guideline is solely for explaining correct procedure reporting and does not imply coverage and reimbursement.**

#### DESCRIPTION

Glioblastoma (GBM) is a fast-growing glioma that develops from glial cells in the brain. GBM is the most prevalent and malignant intracranial tumor, representing as much as 30% of primary brain tumors. The overall prognosis is poor, even with the best standard of care. With optimal treatment, the median survival time is approximately 10 to 14 months. Only a third of patients survive for 1 year following diagnosis of GBM, and < 5% live beyond 5 years. Patients with recurrent GBM have a median survival time of just 5 to 7 months.

The incidence of GBM has been shown to increase with age, and is more common in men than women. Exposure to therapeutic or high-dose radiation and rare familial syndromes has been linked to GBM. The current standard of care for newly diagnosed GBM patients is debulking surgery, followed by combination chemotherapy using temozolomide (TMZ) and radiation therapy. Virtually all patients with newly diagnosed GBM relapse despite best available treatment, with a median time to recurrence of approximately 7 months. At the time of disease recurrence, treatment options for GBM patients are limited. Approximately 20% of patients may undergo repeat surgery. Carmustine polymer wafers may be placed intraoperatively in the surgical cavity during repeat surgery. Rarely, patients may undergo reirradiation. For the majority of recurrent GBM patients, chemotherapy is indicated. In the United States, combination treatment with chemotherapy and the angiogenesis inhibitor bevacizumab has been approved for recurrent GBM and certain other cancers. However, approximately 40% to 60% of recurrent GBM patients are either unresponsive to bevacizumab or experience serious adverse events following treatment.

Optune (formerly the NovoTTF-100A System) (Novocure, Portsmouth, NH) is a novel device that emits alternating electric fields, called tumor treatment fields (TTF), that disrupt the rapid cell division exhibited by cancer cells. It has been approved for use in patients with recurrent glioblastoma (GBM) or as a concomitant treatment with temozolomide (TMZ) in patients with newly diagnosed GBM. Its use has also been investigated within clinical trials in patients with cancers other than GBM, including non-small cell lung cancer (NSCLC).

Optune is a portable battery operated device. Treatment parameters are preset by the device manufacturer and no electrical output adjustments are available to patients. The patient must learn to change and recharge depleted device batteries and to connect to an external power supply overnight. Patients carry the device with them to receive continuous treatment, typically recommended for at least 18 hours per day for a minimum of four weeks. Electrodes must be replaced every few days and the scalp reshaved in order to maintain optimal contact.

NovoTAL (Novocure, Portsmouth, NH) is optional software that a physician can purchase and create individualized treatment maps for patients starting Optune. It is performed in-office and uses MRI head morphology, tumor size and location measurements, and tissue di-electric properties to optimize TTF distribution and intensity within the brain tumor. The physicians are required to complete training and certification in order to use the NovoTAL System. The Optune device is available preset from Novocure. The published literature does not indicate that the use of the software for treatment planning with Novotal is superior to using Optune with preset settings or that it improves clinical outcomes.

#### POLICY

**Tumor treatment field (TTF) therapy (i.e., Optune) (E0766) requires prior authorization for all product lines.**

**Treatment planning software (i.e., NovoTAL) for use with TTF therapy is non-covered for all product lines.**

#### HMO, PPO, Individual Marketplace, Elite, Advantage

TTF therapy (i.e., Optune) is considered medically necessary for individuals 22 years of age or older for the following indications:

- Combined TTF and temozolomide in individuals with histologically confirmed newly diagnosed GBM limited to the supratentorial region following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy

OR

- Monotherapy for individuals diagnosed with histologically or radiologically confirmed recurrent GBM limited to the supratentorial region following treatment with chemotherapy after surgical and radiation treatments have been exhausted

TTF therapy is considered investigational and not medically necessary when the criteria above are not met and for all other malignant tumors.

Treatment planning software (i.e., NovoTAL) for use with TTF therapy for any indication is considered experimental, investigational or unproven.

## CODING/BILLING INFORMATION

The appearance of a code in this section does not necessarily indicate coverage. Codes that are covered may have selection criteria that must be met. Payment for supplies may be included in payment for other services rendered.

### HCPCS CODES

<b>A4555</b>	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
<b>E0766</b>	Electrical stimulation device used for cancer treatment, includes all accessories, any type

**TAWG REVIEW DATES:** 05/27/2016, 08/25/2017

## REVISION HISTORY EXPLANATION

**05/27/16:** Policy created to reflect most current clinical evidence per The Technology Assessment Working Group (TAWG).

**08/25/17:** Tumor treatment field therapy (E0766) is now covered with prior authorization for all product lines. Treatment planning software (i.e., NovoTAL) for use with TTF therapy for any indication is non-covered for all product lines. Policy reviewed and updated to reflect most current clinical evidence per The Technology Assessment Working Group (TAWG).

**Please refer to the member's benefit document for specific information. To the extent there is any inconsistency between this policy and the terms of the member's benefit plan or certificate of coverage, the terms of the member's benefit plan document will govern.**

**Benefits must be available for health care services. Health care services must be ordered by a physician, physician assistant, or nurse practitioner. Health care services must be medically necessary, applicable conservative treatments must have been tried, and the most cost-effective alternative must be requested for coverage consideration.**

**This policy applies to PAS members only when the employer group has elected to provide benefits for the service/procedure/device. Check benefits in SPD/COC. If benefits not specifically addressed in the SPD/COC verify with the appropriate account manager the availability of benefits.**

## PURPOSE:

To provide coverage guidelines for durable medical equipment (DME), prosthetics, orthotics, and non-durable supplies.

## POLICY:

PCHP/PIC or applicable PAS Plan Administrator will cover medically necessary, physician prescribed equipment, supplies, orthotics, prosthetics, and services a member requires for the therapeutic treatment of an accident or illness subject to the guidelines listed below when eligible under the applicable PCHP/ PIC or Plan Administrator eligible DME, orthotics, prosthetics and supplies (DMEPOS) list. Questions regarding eligibility and/or prior authorization requirements should be directed to the Customer Service department. The appropriate telephone number is listed on the back the member's insurance card.

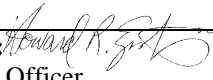

## GUIDELINES:

I. Eligible DME, orthotics, prosthetics, and supplies must satisfy all of the following: A-D

- A. Prior authorized as medically necessary by the Integrated Healthcare Services department when billed charges for purchase exceed \$5000, or as otherwise designated on the DMEPOS List.

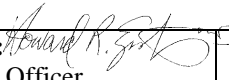

[Note: Unless otherwise designated, rent-to-purchase items do not require prior authorization, even if the purchase price would exceed \$5000.]

<b>Department of Origin:</b> Integrated Healthcare Services	<b>Approved by:</b>  Chief Medical Officer	<b>Date approved:</b> 01/10/18
<b>Department(s) Affected:</b> Claims, Coding, Customer Service, and Integrated Healthcare Services	<b>Effective Date:</b> 01/24/18	
<b>Medical Policy Document:</b> Durable Medical Equipment, Prosthetics, Orthotics, and Supplies (DMEPOS)	<b>Replaces Effective Policy Dated:</b> 03/03/17	
<b>Reference #:</b> MP/D004	Page 2 of 6	

- B. The acceptable standard model that is medically necessary for the member's medical condition. Unacceptable, non-standard models that are not medically necessary include, but are not limited to, the following: 1 and 2
  - 1. DMEPOS that is not proven to be effective by scientific medical literature, and does not demonstrate benefit over standard, less costly equipment; and
  - 2. Any more costly device, which falls under the FDA classification as substantially equivalent to another less costly device.
- C. Ordered for the therapeutic treatment of an accident or illness; to support *activities of daily living*, when required by the COC/SPD. The item is not used primarily for convenience, activities related to leisure, recreation or employment.
- D. Equipment, prosthetics, orthotics, supplies, and services being ordered by a physician is for the treatment of conditions that are allowable by benefits (ie, a chiropractor can only order supplies or equipment used to treat acute musculoskeletal conditions when benefits limit the services of chiropractors to the treatment of acute musculoskeletal conditions)
- E. The frequency is within the allowable quantity limits reflected on the DMEPOS List, unless otherwise specified.
- II. Payment is limited to the most cost effective and medically necessary alternative. When the member purchases a model that is more expensive than what is considered medically necessary the member will be responsible for the difference in purchase and maintenance cost.
- III. Payment for rental shall not exceed the purchase price, unless the item is appropriate for rental only, as designated in this policy. PCHP, PIC, applicable Plan Administrator or designee reserve the right for its medical director or designee to determine if an item will be approved for rental or purchase.
- IV. If a member purchases new equipment or supplies when PCHP, PIC, applicable Plan Administrator or designee determines the repair costs of the member's current equipment or supplies would be more cost effective, then the member will be responsible for the difference in cost.
- V. Payment for repair or replacement of equipment is based on the length of time the equipment has been in service. Payment will not be made for equipment and services when items are damaged or destroyed by the member's misuse, abuse or carelessness; or if they are lost or stolen. Payment will be made only if any of the following apply: A or B
  - A. The equipment is not functioning properly from normal wear and tear and not repairable by the vendor; or
  - B. The physician orders a replacement device or part because of any of the following: 1 or 2
    - 1. A change in the physiological condition of the member; or
    - 2. The condition of the device, or part of the device, requires repairs and the cost of such repairs would be more than 60% of the cost of a replacement device, or of the part being replaced.
- VI. The fact that a provider has prescribed, or recommended an item does not guarantee that the item is medically necessary and/or a covered benefit under the terms of the member's benefit plan.

<b>Department of Origin:</b> Integrated Healthcare Services	<b>Approved by:</b>  Chief Medical Officer	<b>Date approved:</b> 01/10/18
<b>Department(s) Affected:</b> Claims, Coding, Customer Service, and Integrated Healthcare Services	<b>Effective Date:</b> 01/24/18	
<b>Medical Policy Document:</b> Durable Medical Equipment, Prosthetics, Orthotics, and Supplies (DMEPOS)	<b>Replaces Effective Policy Dated:</b> 03/03/17	
<b>Reference #:</b> MP/D004	Page 3 of 6	

VII. All physician-prescribed, medically appropriate and necessary equipment and supplies used in the management and treatment of all forms of diabetes are covered for those plans subject to Minnesota benefit mandates. However, coverage is limited to the most cost-effective acceptable standard equipment.

VIII. Custom-made braces are eligible for coverage only when off-the-shelf items cannot be modified to fit or function properly.

IX. Rental only:

A. PCHP or PIC

1. PCHP or PIC reserves the right for its medical director or designee to determine when an item is appropriate for rental only.
2. PCHP or PIC payment for the following will be considered for rental only reimbursement and not purchase, or rent to purchase; due to frequent and substantial servicing necessary to assure patient safety and positive clinical outcomes.

B. PAS - check SPD for PAS benefits for DME reimbursement, and with appropriate account manager for Plan Administrator position on rental only.

C. The vendor assumes responsibility and liability for duplicates, maintenance, servicing, replacement and supplies necessary for the safety and operation of the item (e.g. breathing circuit, filters, PEEP valve, sterile water, tubing, heated wire circuit, water trap, water chamber etc.).

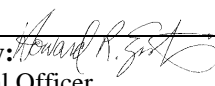

D. Duplicate rental fees for back up ventilators are not eligible, however, rental for a portable in addition to a stationary ventilator may be allowed if medically necessary.

E. Rental only DME may be reviewed periodically for the medical necessity of continued use. The following list is not all-inclusive and current only to the approval date of this policy.

### Rental Only List

DME	HCPCS code
<b>Oxygen and Related Respiratory Equipment</b>	
Stationary compressed gaseous system, includes container, contents, regulator, flowmeter, humidifier, nebulizer, cannula or mask and tubing	E0424
Portable gaseous oxygen system, includes portable container, regulator, flow meter, humidifier, cannula or mask and tubing	E0431
Portable liquid oxygen system, includes portable container, supply reservoir, humidifier, flowmeter, refill adapter, contents gauge, cannula or mask, and tubing	E0434
Stationary liquid oxygen system, includes container, contents, regulator, flowmeter, humidifier, nebulizer, cannula or mask and tubing	E0439
Oxygen concentrator	E1390, E1391, E1392, K0671
Oxygen and water vapor enriching system (with or w/o heated delivery)	E1405, E1406
Oxygen conserving device	No code available

Respiratory Assist	
Respiratory Assist Device (RAD), bi-level pressure capability, with backup rate feature, used with invasive or noninvasive interface; when being used in place of a ventilator	E0470, E0471, E0472
Respiratory Assist (continued)	
Ventilator (stationary or portable)	E0450, E0460, E0461, E0463, E0464
Miscellaneous	
Bilirubin (phototherapy) light and supplies (blanket cradle)	E0202, E0280
Breast pump (hospital grade)	E0604
Continuous passive motion device (CPM)	E0935, E0936
Electrical stimulation device used for cancer treatment (also known as NovoTTF-100A system [alternating electric field therapy])	E0766, A4555 (transducer)
Negative pressure wound therapy electrical pump, stationary or portable	E2402
Temporary replacement for patient-owned equipment being repaired	K0462

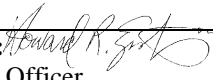

X. Off label use of devices

- A. Off label use of a device that is being investigated as part of a qualifying clinical trial will not be eligible for coverage per guidelines in Medical Policy MP/C008 Oncology Clinical Trials, Covered / Non-Covered Services.
- B. Off label use of devices not in a clinical trial may be approved for one of the following:
  1. Device has unrestricted FDA approval (this does not include Compassionate and Humanitarian FDA approvals)
  2. Published peer reviewed literature supports the therapeutic benefit or diagnostic value

**EXCLUSIONS:**

- I. Refer to the member's Certificate of Coverage or Summary Plan Description for benefits, limitations, and exclusions and the applicable Durable Medical Equipment, Prosthetic, Orthotic, and Supply eligibility list.
- II. Typical plan exclusions include: A-L
  - A. Duplicate or similar items.
  - B. Items which are primarily educational in nature or for vocation, comfort, convenience, or recreation.
  - C. Communication aids or devices; equipment to create, replace or augment communication abilities including, but not limited to, speech processors, receivers, communication board, or computer or electronic assisted communication.

<b>Department of Origin:</b> Integrated Healthcare Services	<b>Approved by:</b>  Chief Medical Officer	<b>Date approved:</b> 01/10/18

<b>Reference #:</b> MP/D004	Page 5 of 6	

- D. Household equipment, household fixtures and modifications to the structure of the home, escalators or elevators, ramps, swimming pools, whirlpools, hot tubs and saunas, wiring, plumbing or charges for installation of equipment, exercise cycles, air purifiers, central or unit air conditioners, water purifiers, hypoallergenic pillows, mattresses or waterbeds.
- E. Vehicle/car or van modifications including, but not limited to, hand brakes hydraulic lifts and car carrier.
- F. Over-the-counter orthotics and appliances.
- G. Custom molded foot orthotics.
- H. Orthopedic shoes, except for members with diabetes or peripheral vascular disease.
- I. Items ordered for activities beyond *activities of daily living*, when required by COC/SPD
- J. Charges for sales tax, mailing and delivery.
- K. Items listed as not covered on the DMEPOS List.
- L. Items on the Investigative List.

## DEFINITIONS:

### Activities of Daily Living (ADL):

Physical functions that an independent person performs each day, including bathing, dressing, eating, toileting, walking or wheeling, and transferring into and out of bed. This is equal to a functional ambulation level 1 or 2 for lower limb prosthesis requests. ADLs do not include activities related to leisure, recreation or employment.

### Durable Medical Equipment:

A piece of equipment for a specific therapeutic purpose in the treatment of an illness and that can withstand repeated use and is not disposable; is primarily and customarily used to serve a medical purpose; generally would not be useful to the member in the absence of an illness.

### Healthcare service:

A medical or behavioral pharmaceutical, device, technology, treatment, supply, or procedure

### Non-Durable Equipment/Supplies:

Medical supplies for a specific therapeutic purpose in the treatment of an illness or injury, or are needed for the operation of approved *durable medical equipment* and that are disposable and usually used only one time.

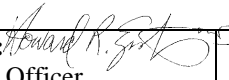

### Orthotic Device:

Rigid or semi-rigid devices used to support a weak or deformed body part or to restrict or eliminate motion in a diseased or injured body part.

### Off Label Use:

Device/equipment/drug used in a manner that is different from its approved purpose

<b>Department of Origin:</b> Integrated Healthcare Services	<b>Approved by:</b>  Chief Medical Officer	<b>Date approved:</b> 01/10/18

## PreferredOne Community Health Plan Nondiscrimination Notice

PreferredOne Community Health Plan ("PCHP") complies with applicable Federal civil rights laws and does not discriminate on the basis of race, color, national origin, age, disability, or sex. PCHP does not exclude people or treat them differently because of race, color, national origin, age, disability, or sex.

### PCHP:

Provides free aids and services to people with disabilities to communicate effectively with us, such as:

- Qualified sign language interpreters
- Written information in other formats (large print, audio, accessible electronic formats, other formats)

Provides free language services to people whose primary language is not English, such as:

- Qualified interpreters
- Information written in other languages

If you need these services, contact a Grievance Specialist.

If you believe that PCHP has failed to provide these services or discriminated in another way on the basis of race, color, national origin, age, disability, or sex, you can file a grievance with:

Grievance Specialist  
PreferredOne Community Health Plan  
PO Box 59052  
Minneapolis, MN 55459-0052  
Phone: 1.800.940.5049 (TTY: 763.847.4013)  
Fax: 763.847.4010  
[customerservice@preferredone.com](mailto:customerservice@preferredone.com)

You can file a grievance in person or by mail, fax, or email. If you need help filing a grievance, a Grievance Specialist is available to help you.

You can also file a civil rights complaint with the U.S. Department of Health and Human Services, Office for Civil Rights, electronically through the Office for Civil Rights Complaint Portal, available at <https://ocrportal.hhs.gov/ocr/portal/lobby.jsf>, or by mail or phone at:

U.S. Department of Health and Human Services

## Introduction

Tumor treating fields (TTF) is a new treatment being studied for use in certain cancers. The therapy consists of low-level electrical currents that arise from small insulated electrodes placed on the skin surface. TTF is believed to cause cell death during a later stage of development. Currently this therapy is covered as one treatment option for people who have a deadly form of brain cancer called glioblastoma multiforme. People wear a helmet with small electrodes attached to the scalp for at least 18 hours per day during TTF therapy. This treatment requires pre-approval by the plan, and this policy describes when this treatment is covered. TTF is considered investigational for other types of cancer (therefore not covered), as there is not yet enough scientific data that shows it works for other diagnoses.

**Note:** The Introduction section is for your general knowledge and is not to be taken as policy coverage criteria. The rest of the policy uses specific words and concepts familiar to medical professionals. It is intended for providers. A provider can be a person, such as a doctor, nurse, psychologist, or dentist. A provider also can be a place where medical care is given, like a hospital, clinic, or lab. This policy informs them about when a service may be covered.

## Policy Coverage Criteria

Condition	Investigational
<b>Glioblastoma- initial therapy</b>	<b>Tumor treating fields (TTF) to treat glioblastoma is considered investigational:</b> <ul style="list-style-type: none"> <li>As an alternative to standard chemotherapy for patients with advanced or recurrent glioblastoma</li> </ul>
<b>All other diagnoses</b>	<b>Tumor treating fields (TTF) is considered investigational for all other indications.</b>

Condition	Medical Necessity
<b>Glioblastoma- adjuvant therapy</b>	<b>Tumor treating fields (TTF) to treat glioblastoma is medically necessary when all of the following are met:</b> <ul style="list-style-type: none"> <li>Initial treatment with debulking surgery or biopsy, followed by concurrent temozolamide</li> </ul> <b>AND</b> <ul style="list-style-type: none"> <li>Radiotherapy, with no documented tumor progression</li> </ul> <b>AND</b> <ul style="list-style-type: none"> <li>TTF is used with temozolamide</li> </ul> <b>AND</b> <ul style="list-style-type: none"> <li>TTF is begun within 7 weeks of final radiation treatment</li> </ul>

## Coding

HCPCS	
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only
A9900	Miscellaneous DME supply, accessory, and/or service component of another HCPCS code
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type
E1399	Durable medical equipment, miscellaneous

**Note:** CPT codes, descriptions and materials are copyrighted by the American Medical Association (AMA). HCPCS codes, descriptions and materials are copyrighted by Centers for Medicare Services (CMS).

## Related Information

None

## Evidence Review

### Background

#### *Glioblastome Multiforme*

Glioblastomas, also known as glioblastoma multiforme (GBM), are the most common form of malignant primary brain tumor in adults. They comprise approximately 15% of all brain and central nervous system tumors, and more than 50% of all tumors that arise from glial cells.<sup>1</sup> The peak incidence for GBM occurs between the ages of 45 and 70 years. GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy.<sup>1</sup> According to the National Comprehensive Cancer Network, "only a third of patients [with GMB] surviv[e] for 1 year and less than 5% liv[e] beyond 5 years."<sup>2</sup>

#### *Treatment of Glioblastoma Multiforme*

The primary treatment for initial GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (bis-chloroethylnitrosourea [BCNU]).impregnated wafer.<sup>2</sup> Depending on the patient's physical condition, adjuvant radiotherapy, chemotherapy (typically temozolomide), or a combination of the 2 are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide.

No standard treatment exists for recurrent GBM. After these initial treatments, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, BCNU/chloroethylnitrosourea [CCNU], temozolomide), temozolomide, nitrosourea, PCV (procarbazine, CCNU, vincristine), cyclophosphamide, and platinum-based agents.<sup>2</sup> External beam radiotherapy also may be used. Response rates in

recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.<sup>2,3</sup>

## ***Tumor Treating Fields***

TTF therapy is a new, noninvasive technology intended to treat GBM on an outpatient basis using electrical fields.<sup>3-5</sup> TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by two mechanisms: arrest of cell proliferation and destruction of cells while undergoing division.<sup>4,5</sup>

The NovoTTF-100A System has received marketing approval from the U.S. Food and Drug Administration to deliver TTF therapy. TTF therapy via the NovoTTF-100A System is delivered by a battery-powered, portable device that generates the fields via disposable electrodes noninvasively attached to the patient's shaved scalp over the site of the tumor.<sup>3,4</sup> The device is used by the patient at home on a continuous basis (20-24 h/d) for the duration of treatment, which can last for several months. The device is covered under the DME benefit. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.<sup>3,4</sup>

## **Evidence Review**

This evidence review was created in August 2013 and has been updated periodically through literature searches of the MEDLINE database. The most recent literature review was through March 24, 2016.

Following is a summary of the key literature. Tumor treating fields (TTF) therapy is proposed as a treatment for glioblastoma multiforme (GBM). For this review, 2 indications will be considered: (1) TTF therapy as an alternative to chemotherapy in advanced or recurrent GBM and (2) TTF therapy as an adjunct to maintenance treatment in patients following early treatment. Comparative trials are essential to determine efficacy in this area, and randomized controlled trials (RCTs) are needed to control for heterogeneity in the patient populations and other confounders of outcome. This evidence review will include both RCTs and nonrandomized comparative trials.

## TTF Therapy as an Alternative to Chemotherapy in Advanced or Recurrent GBM

### *Randomized Controlled Trials*

The U.S. Food and Drug Administration (FDA) approval of the NovoTTF-100A system was based on a Phase III, multinational prospective randomized controlled trial (RCT) (EF11) which was published in 2012 by Stupp et al.<sup>3</sup> The Stupp study, which was sponsored and funded by the manufacturer of the device (NovoCure), compared tumor-treating fields (TTF) therapy (delivered by the NovoTTF-100A System) with the best standard of care chemotherapy (active control). Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive glioblastoma multiforme (GBM), despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status score of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$ second recurrence), and 20% had failed bevacizumab before study enrollment.

Two-hundred thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers. Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosoureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, and a period of 28 days of treatment with TTF was considered one full treatment course.

The primary study endpoint in this RCT was overall survival (OS).<sup>3</sup> Secondary endpoints included progression-free survival (PFS) at 6 months, TTP, one-year survival rate, quality of life (QOL), and radiologic response.

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed one cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device.<sup>3</sup> For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except one individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.

Outcomes of this study are summarized in Table 1. The trial failed to reach its primary endpoint of improved survival compared with active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared with 6.0 months in the active control group (hazard ratio [HR], 0.86; 95% confidence interval [CI], 0.66 to 1.12;  $p=0.27$ ). For both groups, one-year survival was 20%.

Longitudinal QOL data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration.

Wong et al published a subgroup analysis of the Stupp RCT to determine characteristics of responders and nonresponders in the treatment and active control groups.<sup>9</sup> Tumor response was assessed using Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm (7.3 months) than those in the chemotherapy arm (5.6 months;  $p<0.001$ ), and there was a strong correlation (Pearson  $r$ ) between response and OS in the TTF arm ( $p<0.001$ ) but not in the chemotherapy arm ( $p=0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

In summary, this RCT failed to demonstrate the primary endpoint of improved survival with TTF therapy in comparison with chemotherapy.<sup>3,9</sup> Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of one or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy. The latter study design is being used in an ongoing trial of TTF therapy in the treatment of patients with newly diagnosed GBM (see [Ongoing and Unpublished Clinical Trials](#) ).

A further limitation was high dropout rates in both groups. For example, over 20% of participants in the active control group were lost at follow-up, and this degree of the number of dropouts may have underestimated the toxicity evaluation in this group. Similarly, over 20% of participants in the TTF arm discontinued treatment within a few days due to noncompliance or inability to handle the device. This implies that compliance might be an issue with TTF, because it requires the patient to continuously wear transducers on the shaved head. Finally, the number of patients who completed the QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators may have been subject to bias due to the lack of blinding.<sup>3,6</sup>

**Table 1. Principal Efficacy Results for Randomized Trial of TTF Therapy versus Physicians' Choice of Chemotherapy in Recurrent Glioblastoma (Stupp et al)**

Outcomes	TTF	Chemotherapy	Measure of Association, Significance
Median survival, mo	6.6	6.0	
Hazard ratio for survival			0.86 (95% CI, 0.66 to 1.12) favors TTF
Radiologic response (not all patients evaluated)	14%	9.6%	p=0.19
Median PFS, mo	2.2	2.1	
Hazard ratio for PFS			0.81 (95% CI, 0.60 to 1.09) favors TTF

CI: confidence interval; PFS: progression-free survival; TTF: tumor treating fields.

A second post hoc analysis of the TTF EF-11 pivotal trial data was performed to evaluate OS rates among patients who completed at least one complete course of TTF or chemotherapy.<sup>10</sup> These investigators analyzed survival in what they referred to as a "modified ITT [intention-to-treat]" subgroup comprising 93 of 120 (78%) of the original TTF allocated group, versus 117 of 117 (100%) of the original chemotherapy allocated group. This exercise revealed median OS of 7.7 months in the TTF modified ITT (mITT) group compared with 5.9 months in the chemotherapy group (HR=0.69; 95% CI: 0.52 to 0.91; p=0.009). They also showed a trend relationship between proportion of patients with higher TTF compliance and median OS rates (p=0.039). The investigators suggest that TTF provides an OS benefit if used as intended in the

FDA-approved label when compared with best chemotherapy. This post hoc analysis has flaws in that it was not pre-specified in the study, includes only 78% of the original TTF allocated patients, and fails to control for noncompliance due to faster clinical deterioration of TTF recipients leading to treatment cessation.

### ***Nonrandomized Comparative Studies***

Two nonrandomized studies were identified that compared TTF treatment to standard care using historical controls. A study published in late 2014 assessed OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting at 91 centers in the United States between October 2011 and November 2013.<sup>11</sup> Median OS rate in the PRiDe clinical practice dataset (9.6 months) was reported as significantly superior to that attained in the TTF EF-11 pivotal trial (6.6 months; HR=0.66, 95% CI, 0.05 to 0.86;  $p<0.001$ ). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the EF-11 trial (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the EF-11 trial.

Kirson et al (2007) reported findings of a study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent GBM.<sup>12</sup> Median TTP in these patients was 26.1 weeks, and median OS was 62.2 weeks. The authors noted that these TTP and OS rates were more than double the medians reported for historical control patients. No device-related serious adverse events were seen after more than 70 months of cumulative treatment in all patients. The only device-related adverse event observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was its use of historical controls, because those patients may not be comparable on major clinical and prognostic features.<sup>12</sup>

### **Section Summary: TTF Therapy as an Alternative to Chemotherapy in Advanced or Recurrent GBM**

The single RCT for this indication reported that outcomes following TTF therapy were similar to outcomes following standard chemotherapy. However, this RCT is not sufficient to allow conclusions on the efficacy of the device. There was no placebo control group or supportive care treatment group, and treatments used in the active control arm (best standard of care chemotherapy) have previously demonstrated limited efficacy. Thus, the comparisons made have limited ability to determine the true treatment effect of TTF. Methodologic limitations in

the study decrease its' internal validity. There was heterogeneity in the patient populations and heterogeneity in the chemotherapy regimens for the control group. Furthermore, more patients in the TTF group than in the control group did not complete the treatment course, and patients in the TTF group received more courses of second-line chemotherapy. The number of patients who completed the QOL data was approximately one-quarter of total enrollment and the self-reported QOL indicators may have been subject to bias due to the lack of blinding.<sup>3,6</sup> The other available published evidence, 2 nonrandomized comparative studies, are small and limited by potential differences in patient populations. Thus, the evidence base does not permit conclusions about the impact of the technology on health outcomes.

## TTF Therapy as an Adjunct to Standard Maintenance Care for GBM

In 2015, Stupp et al published a planned interim analysis of a multicenter, open-label RCT that evaluated maintenance therapy with TTF for GBM.<sup>13</sup> This trial enrolled patients with GBM who had completed standard treatment consisting of chemoradiotherapy plus surgery if indicated. Patients were randomized in a 2:1 fashion to receive TTF plus temozolomide or temozolomide alone. At the time of the interim analysis, 210 patients were randomized to TTF plus temozolomide and 105 patients randomized to temozolomide alone. The primary outcome was PFS analyzed by intention-to-treat; a secondary outcome was OS analyzed by per-protocol analysis. Planned interim analysis was performed at a median follow-up of 38 months (range, 18-60 months). Median PFS and median OS are summarized in Table 2.

**Table 2. TTF Therapy as an Adjunct to Standard Maintenance Care in Glioblastoma**

Group	N	PFS (95% CI)	HR (98.7% CI)	OS (95% CI)	HR (99.4% CI)
TTF + temozolomide	210 (196a)	7.1 mo (5.9 to 8.2 mo)	0.62 (0.43 to 0.89)	20.5 mo (16.7 to 25 mo)	0.64 (0.42 to 0.98)
Temolozolomide alone	105 (84a)	4.0 mo (3.3 to 5.2 mo)		15.6 mo (13.3 to 19.1 mo)	

CI: confidence interval; HR: hazard ratio; OS: overall survival; PFS: progression-free survival; TTF: tumor treating fields.<sup>a</sup>  
Included in per-protocol analysis.

There were a total of 35 (11%) dropouts during the trial, 14 (6.7%) of 210 patients in the TTF group and 21 (20%) of 105 in the temozolomide alone group. Adherence to treatment was defined as wearing the device for at least 18 hours a day, and 157 (75%) of 210 patients met this criteria for adherence. The number of treatment cycles with temozolomide differed between groups. The TTF group received a median of 6 cycles compared to a median of 4 cycles for the temozolomide alone group. The most common side effect of treatment was local skin irritation, which occurred in 43% of patients treated with TTF.

### ***Section Summary: TTF Therapy as an Adjunct to Standard Maintenance Care for GBM***

The single RCT for this indication reported that PFS improved by 3.1 months and OS improved by 4.9 months following the addition of TTF to standard maintenance therapy. Therefore, there may be a survival benefit associated with TTF therapy for this indication, but there is substantial uncertainty around this conclusion. The single RCT had methodologic limitations and the current publication is a planned interim analysis. The lack of a placebo group and the lack of blinding create the possibility of a placebo effect, even with the survival outcomes. There was a moderately high rate of dropouts overall (11%) and differential dropout between groups (6.7% in the TTF group vs 20% in standard maintenance group). Also, for outcomes evaluated on a per-protocol basis (e.g., OS), there is the possibility of an adherence bias, in that patients who complete the treatment protocol may have better outcomes than patients who do not. As a result, conclusions about the efficacy of TTF therapy for this indication cannot be made with certainty.

### **Ongoing and Unpublished Clinical Trials**

Some currently unpublished trials that might influence this review are listed in Table 3.

**Table 3. Summary of Key Trials**

NCT No.	Trial Name	Planned Enrollment	Completion Date
Ongoing			

<b>NCT01894061<sup>a</sup></b>	A Prospective Phase II Trial of NovoTTF-100A With Bevacizumab (Avastin) in Patients With Recurrent Glioblastoma	40	October 2016
<b>NCT01755624<sup>a</sup></b>	A Phase II Randomized Study of TTFeld Therapy Versus Supportive Care in Non-small Cell Lung Cancer Patients With 1-5 Brain Metastases Following Optimal Standard Local Treatment	60	July 2017
<b>NCT01756729<sup>a</sup></b>	A Prospective, Non-randomized, Concurrent Control, Open Label, Post-approval Study of NovoTTF-100A in Recurrent GBM Patient	486	January 2018
<b>NCT01954576</b>	A Phase II Study of the NovoTTF-100A system, Enhanced by Genomic Analysis to Identify the Genetic Signature of Response in the Treatment of Recurrent Glioblastoma Multiforme	30	May 2018

NCT: national clinical trial. <sup>a</sup> Denotes industry-sponsored or cosponsored trial.

## Summary of Evidence

Glioblastoma multiforme (GBM) is the most common and deadly malignant brain tumor. It has a very poor prognosis and is associated with low quality of life during treatment. Tumor treating fields (TTF).

For individuals who have advanced or recurrent glioblastoma multiforme (GBM) who receive tumor treating fields (TTF) therapy as an alternative to standard chemotherapy, the evidence consists of 1 randomized controlled trial (RCT) and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single published RCT reported no difference in outcomes between patients treated with TTF therapy and standard chemotherapy. This trial has methodologic limitations. The comparisons made included only an active control of questionable efficacy, which may not reflect current standard of care. More patients in the TTF group than in the control group did not complete the treatment course, and patients in the TTF group received more courses of second-line chemotherapy. For the quality of life outcomes, only approximately one-quarter of enrolled patients had complete data. The 2 nonrandomized studies were small, with limited validity due to differences in the patient populations treated with TTF and standard care. The evidence is insufficient to determine the effects of the technology on health outcomes.

For individuals who have GBM on maintenance therapy following initial treatment with surgery and/or radiotherapy who receive TTF therapy as an adjunct to maintenance treatment following initial treatment with surgery and/or radiation, the evidence consists of 1 RCT. Relevant

outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT reported that patients who received TTF therapy plus temozolomide have longer progression-free survival (3.1 months) and overall survival (4.9 months) than patients who received temozolomide alone. The trial had methodologic limitations, therefore further high-quality RCTs are needed to validate the results. The evidence is insufficient to determine the effects of the technology on health outcomes.

## Practice Guidelines and Position Statements

The National Comprehensive Cancer Network's Central Nervous System Tumors guidelines (v.1.2016)<sup>2</sup> has updated the recommendation for the treatment of recurrence of glioblastoma, with the option "consider alternating electric field therapy for glioblastomas" from a Category 3 recommendation to a 2A recommendation for adjuvant therapy, and 2B for use in recurrent disease.

## Medicare National Coverage

There is no National Coverage Decision (NCD). In the absence of an NCD, coverage decisions are left to the discretion of local Medicare carriers.

## Regulatory Status

The NovoTTF-100A™ System (assigned the generic name of TTF) was approved by FDA in April 2011 through the premarket approval process.<sup>6</sup> The FDA-approved label reads as follows:

"The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed GBM, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."<sup>6</sup>

On September 28, 2014, FDA approved a request for Novocure to change its products name from NovoTTF-110A System to Optune™.<sup>7</sup>

On October 15, 2015, FDA granted approval for the use of Optune in combination with temozolomide for newly diagnosed supratentorial glioblastoma, after maximal debulking surgery , radiation and standard chemotherapy<sup>8</sup>

Product code: NZK.

## COVERAGE RATIONALE

The use of U.S. Food and Drug Administration (FDA) approved devices to generate electric tumor treatment fields (TTF) to treat newly diagnosed histologically-confirmed Supratentorial glioblastoma (known also as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) is proven and medically necessary when used according to FDA labeled indications, contraindications, warnings and precautions, and when ALL of the following criteria are met:

- Initial treatment with radiation therapy has been completed; and
- Individual is receiving Temozolomide; and
- Individual has a Karnofsky Performance Status (KPS) score of  $\geq 60$ ; and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

### Recurrent GBM

The use of FDA approved devices to generate electric TTF is proven and medically necessary following radiologically-confirmed recurrence of GBM in the supratentorial region of the brain after initial chemotherapy and when ALL of the following criteria are met:

- The device is used as a monotherapy
- Individual has a KPS score of  $\geq 60$ ; and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

When all of the above criteria are met for either newly diagnosed or recurrent GBM, an initial 3 months of electric TTF therapy will be approved.

Subsequent approval(s) for continuation of electric TTF is based on:

- MRI scan has been performed  $\leq 2$ -4 months prior to request and documents no evidence of disease progression. ; and
- KPS score of  $\geq 60$ ; and
- Documentation that the individual has been wearing the device at least 18 hours daily.

The use of devices to generate electric tumor treatment fields (TTF) is considered investigational, unproven, and not medically necessary when the criteria above are not met and for all other indications. The FDA has not approved the use of electric TTF devices for indications other than GBM. Further studies are needed to determine the safety and long-term efficacy of electric TTF therapy for other types of cancer.

Computer software used for therapeutic radiology clinical treatment planning in conjunction with electric tumor treatment field (TTF) therapy is unproven and not medically necessary.

There is insufficient evidence to establish the efficacy of these products in the long-term outcomes of patients receiving electric TTF therapy.

## DEFINITIONS

**Karnofsky Performance Status (KPS):** A standard way of measuring the ability of cancer patients to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily

activities. For example, a KPS of 60 means a person requires occasional assistance, but is able to care for most of their personal needs. KPS may be used to determine a patient's prognosis, to measure changes in a patient's ability to function, or to decide if a patient could be included in a clinical trial (National Cancer Institute [NCI], 2018).

**Supratentorial:** The upper portion of the brain comprised of the cerebrum and the diencephalon (NCI, 2018).

**Temozolomide:** An oral alkylating chemotherapy drug used in the treatment of some brain cancers. It is a first-line treatment for glioblastoma (NCI, 2018).

#### APPLICABLE CODES

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies and Coverage Determination Guidelines may apply.

CPT Code	Description
77299	Unlisted procedure, therapeutic radiology clinical treatment planning <i>CPT® is a registered trademark of the American Medical Association</i>
HCPCS Code	Description
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type

#### DESCRIPTION OF SERVICES

Electric tumor treatment field (TTF) therapy (also known as tumor-treating fields, TTFields, ETTFs) is based on the principle that low intensity, intermediate frequency electric fields (100 to 300 kHz) have an anti-mitotic effect which acts during late metaphase and anaphase, with specific frequencies affecting specific cell types (Rulseh et al, 2012).

Alternating electrical fields within the human body that disrupt the rapid cell division exhibited by cancer cells, with the alternating electrical fields applied to the brain through transducer arrays placed on the scalp. TTF harness electric fields to arrest the proliferation of tumor cells and to destroy them. The TTF technology takes advantage of the special characteristics and geometrical shape of dividing cells, which make them susceptible to the effects of the alternating electric TTFields. These special fields alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used for a particular treatment is specific to the cell type being treated (e.g., 200kHz for GBM). In contrast, the TTFields have not been shown to have an effect on cells that are not undergoing division. Since most normal adult brain cells proliferate very slowly, if at all, they are hypothesized to be little affected by the TTFields (Novocure, 2018).

Glioblastoma multiforme (GBM) is the most prevalent and primary malignant brain tumor in adults, accounting for 54% of all gliomas. GBM is the most lethal brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years. Unfortunately most glioblastomas recur (National Comprehensive Cancer Network [NCCN], 2018). It develops from star-shaped glial cells (astrocytes and oligodendrocytes) that support the health of the nerve cells within the brain.

The mainstay of treatment for GBM is surgery, followed by radiation and chemotherapy. The primary objective of surgery is to remove as much of the tumor as possible without injuring the surrounding healthy brain tissue needed for normal neurological function (such as motor skills, the ability to speak and walk, etc.). However, GBMs are surrounded by a zone of migrating, infiltrating tumor cells that invade surrounding tissues, making it impossible to ever remove the tumor entirely. Surgery provides the ability to reduce the amount of solid tumor tissue within the brain, remove those cells in the center of the tumor that may be resistant to radiation and/or chemotherapy and reduce intracranial pressure (American Association of Neurological Surgeons [AANS], 2018).

The Optune®, formerly the NovoTTF-100A System, (Novocure, Portsmouth NH) was approved by the FDA in April 2011, as a novel device to treat adults age 22 years or older with GBM that recurs or progresses after receiving chemotherapy and radiation therapy.

A supplemental FDA premarket approval was received in October 2015 for Optune™ with Temozolomide in adult patients with newly diagnosed, Supratentorial glioblastoma following maximal debulking surgery and completion of

radiation therapy together with concomitant standard of care chemotherapy. For newly diagnosed GBM, Optune is not intended to be used as a substitute for standard treatments but rather as an adjunct therapy.

Refer to the U.S. Food and Drug Administration (FDA) section for additional information.

The Optune kit contains the portable electric field generator (Optune device), INE (insulated electrode) transducer arrays, power supply, and additional supplies. Prior to treatment, transducer arrays are placed on the patient's scalp according to the tumor's location, which are then covered by a lightweight white cap which resembles a bandage. The patient receives the noninvasive TTF treatment for at least 18 continuous hours per day for a minimum of 4 weeks. As the Optune device is portable, patients are able to carry out every-day activities.

Treatment parameters are preset by the manufacturer such that there are no electrical output adjustments available to the patient. The patient or caregiver must learn to change and recharge depleted device batteries and to connect to an external power supply overnight. In addition, the transducer arrays need to be replaced once to twice a week and the scalp re-shaved in order to maintain optimal contact.

The NovoTAL™ (transducer array layout) system is optional simulation software for use in clinical treatment planning with Optune therapy that may be leased from the manufacturer. Its purpose is to determine the optimal location of the transducer arrays based on the patient's most recent magnetic resonance imaging (MRI) scan, head size, and tumor location.

TTF technology is also being studied through ongoing clinical trials as a treatment for other solid tumors such as non-small cell lung cancer, brain metastasis, pancreatic cancer, ovarian cancer, and mesothelioma.

## CLINICAL EVIDENCE

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guideline for Central Nervous System Cancers, anaplastic gliomas/glioblastoma, includes standard brain radiation therapy (RT) + concurrent temozolomide and adjuvant temozolomide + alternating electric field therapy for patients with good performance status and either methylated or unmethylated/indeterminate MGMT promoter status, in whom resection was not feasible with the following footnote: "Alternating electric field therapy is only an option for patients with supratentorial disease" (category 1). For recurrence of GBM (GLIO-5), the guideline includes consideration of alternating electric treatment fields for glioblastoma after surgery, radiation and chemotherapy (category 2B) (NCCN, 2018).

Stupp et al. (2017) reported final outcomes from the randomized, open-label trial of 695 patients with glioblastoma whose tumor was resected or biopsied and had completed concomitant radiochemotherapy (median time from diagnosis to randomization, 3.8 months) and Optune therapy. Of the 695 randomized patients (median age, 56 years; IQR, 48-63; 473 men [68%]), 637 (92%) completed the trial. Median progression-free survival from randomization was 6.7 months in the TTFields-temozolomide group and 4.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.52-0.76;  $P < .001$ ). Median overall survival was 20.9 months in the TTFields-temozolomide group vs 16.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ). Systemic adverse event frequency was 48% in the TTFields-temozolomide group and 44% in the temozolomide-alone group. Mild to moderate skin toxicity underneath the transducer arrays occurred in 52% of patients who received TTFields-temozolomide vs no patients who received temozolomide alone. In the final analysis of this randomized clinical trial of patients with glioblastoma who had received standard radiochemotherapy, the addition of TTFields to maintenance temozolomide chemotherapy vs maintenance temozolomide alone, resulted in statistically significant improvement in progression-free survival and overall survival. These results are consistent with the previous interim analysis.

In a secondary analysis of the Stupp et al. (2017) trial, Taphoorn et al. (2018) examined the association of TTFields therapy with progression-free survival and HRQoL among patients with glioblastoma. Of the 695 patients in the study, 639 (91.9%) completed the baseline HRQoL questionnaire. Of these patients, 437 (68.4%) were men; mean (SD) age, 54.8 (11.5) years. Health-related quality of life did not differ significantly between treatment arms except for itchy skin. Deterioration-free survival was significantly longer with TTFields for global health (4.8 vs 3.3 months;  $P < .01$ ); physical (5.1 vs 3.7 months;  $P < .01$ ) and emotional functioning (5.3 vs 3.9 months;  $P < .01$ ); pain (5.6 vs 3.6 months;  $P < .01$ ); and leg weakness (5.6 vs 3.9 months;  $P < .01$ ), likely related to improved progression-free survival. Time to deterioration, reflecting the influence of treatment, did not differ significantly except for itchy skin (TTFields worse; 8.2 vs 14.4 months;  $P < .001$ ) and pain (TTFields improved; 13.4 vs 12.1 months;  $P < .01$ ). Role, social, and physical functioning were not affected by TTFields. The addition of TTFields to standard treatment with temozolomide for patients with glioblastoma results in improved survival without a negative influence on HRQoL except for more itchy skin, an expected consequence from the transducer arrays.

In a multinational, open-label, randomized phase III trial (EF-14 trial), Stupp et al. (2015) compared Optune in combination with temozolomide to temozolomide alone in 700 patients age 18 and over with newly diagnosed GBM.

The interim report revealed that in the intent-to-treat population, patients treated with TTFields plus temozolomide showed a statistically significant increase in progression free survival (PFS), the primary endpoint, compared to temozolomide alone (median PFS 7.1 months versus 4.0 months, hazard ratio=0.62,  $p=0.0013$ ). In the per-protocol population, patients treated with TTFields plus temozolomide demonstrated a statistically significant increase in OS, a powered secondary endpoint, compared to temozolomide alone (median OS 20.5 months versus 15.6 months, hazard ratio=0.64,  $p=0.0042$ ). In the intent-to-treat population, the median OS was 19.6 months versus 16.6 months, respectively, hazard ratio=0.74 ( $p=0.0329$ ). The two-year survival rate was 50 percent greater with TTFields plus temozolomide versus temozolomide alone: 43 percent versus 29 percent. The trial's independent data monitoring committee concluded that the study met its endpoints at its pre-specified interim analysis of the first 315 patients with 18 months or more of follow-up. The committee recommended that the trial be terminated early for success and that all control patients be offered TTFields therapy even prior to progression. In addition, the authors reported that the trial showed Optune could be safely combined with temozolomide. There was no significant increase in systemic toxicities from Optune reported in combination with temozolomide versus temozolomide alone. The most common adverse reaction from Optune treatment was mild to moderate skin irritation, which according to the authors was easily managed, reversible and did not result in treatment discontinuation. This clinical trial has some important limitations. Patient enrollment occurred only after the end of radiochemotherapy, leading to some variation in the delivery of standard treatment of temozolomide and radiotherapy. Patients who had progressed early during radiochemotherapy were not eligible for randomization, thus excluding patients with very poor prognoses. There is likely reporting bias for second-line therapies after tumor progression because in the TTFields plus temozolomide group, TTFields were to be continued, and thus, more detailed treatment information has been tracked for this group.

Stupp et al. (2012) completed a phase III randomized trial (EF-11 trial) of chemotherapy-free treatment of Novo tumor treatment fields (TTF) (20-24h/day) versus active chemotherapy in the treatment of patients with recurrent glioblastoma. The primary end-point was improvement of overall survival. Patients (median age 54 years (range 23-80), Karnofsky performance status 80% (range 50-100) were randomized to TTF alone ( $n=120$ ) or active chemotherapy control ( $n=117$ ). Number of prior treatments was two (range 1-6). Median survival was 6.6 versus 6.0 months (hazard ratio 0.86 [95% CI 0.66-1.12];  $p=0.27$ ), 1-year survival rate was 20% and 20%, progression-free survival rate at 6 months was 21.4% and 15.1% ( $p=0.13$ ), respectively in TTF and active control patients. Responses were more common in the TTF arm (14% versus 9.6%,  $p=0.19$ ). The TTF-related adverse events were mild (14%) to moderate (2%) skin rash beneath the transducer arrays. Severe adverse events occurred in 6% and 16% ( $p=0.022$ ) of patients treated with TTF and chemotherapy, respectively. Quality of life analyses favored TTF therapy in most domains. Although no improvement in overall survival was demonstrated, the authors conclude that the efficacy and activity with this chemotherapy-free treatment device appears comparable to chemotherapy regimens that are commonly used for recurrent glioblastoma and that toxicity and quality of life favored TTF.

A treatment-based analysis of data from the pivotal phase III trial of the NovoTTF-100A System™ versus best physician's choice (BPC) chemotherapy was conducted by Kanner et al. (2014) in patients with recurrent glioblastoma multiforme (GBM), with particular focus on efficacy in patients using NovoTTF therapy as intended. Median overall survival (OS) was compared for recurrent GBM patients receiving at least one full cycle of treatment with NovoTTF-100A System or BPC chemotherapy (modified intention-to-treat [mITT] population). The relationship between NovoTTF-100A System compliance and OS was evaluated in the ITT population. Kaplan-Meier analyses examined treatment-related differences in OS for various patient subgroups. Median OS was significantly higher in patients receiving  $\geq 1$  course of NovoTTF therapy versus BPC (7.7 v 5.9 months; hazard ratio, 0.69; 95% confidence interval [CI], 0.52-0.91;  $P = .0093$ ). Median OS was also significantly higher in patients receiving NovoTTF therapy with a maximal monthly compliance rate  $\geq 75\%$  ( $\geq 18$  hours daily) versus those with a  $< 75\%$  compliance rate (7.7 v 4.5 months;  $P = .042$ ), and Kaplan-Meier analysis demonstrated a significant trend for improved median OS with higher compliance ( $P = .039$ ). Additional post hoc analysis showed significantly higher median OS with NovoTTF therapy than with BPC for patients with prior low-grade glioma, tumor size  $\geq 18$  cm<sup>2</sup>, Karnofsky performance status  $\geq 80$ , and those who had previously failed bevacizumab therapy. This contrasts with the equivalent efficacy reported previously based on analysis of all randomized ITT subjects, including many who did not receive a full cycle of treatment. The authors summarized that results from the present study suggest that when used as intended, NovoTTF Therapy provides efficacy superior to that of chemotherapy in a heterogeneous population of patients with recurrent GBM. Post hoc analyses identified subgroups of patients who may be particularly good candidates for NovoTTF Therapy, pending further confirmatory studies.

Wong et al, (2015) conducted a retrospective chart review from a single institution on patients treated with NovoTTF-100A and bevacizumab between November 2011 and December 2013. The patients were segregated into two cohorts: (i) those treated with NovoTTF-100A and bevacizumab only and (ii) those treated with NovoTTF-100A, bevacizumab and TCCC. Response to treatment was measured according to the Response Assessment in Neuro-Oncology criteria. Progression-free survival (PFS) and OS were measured from the time of application of these treatments to death or last follow up. The cohort treated with NovoTTF-100A, bevacizumab, and TCCC ( $n = 3$ ) did not differ significantly from the rest of the cohort treated with NovoTTF-100A and bevacizumab only ( $n = 34$ ). Potential reasons for this include baseline clinical characteristics and dexamethasone use. The authors note limitations with this review to be the

number of patients treated with NovoTTF-100A, bevacizumab, and TCCC is small and therefore they cannot recommend this combination as standard clinical practice. However, they commented that the findings in their patients are notable and it can serve as a basis for future clinical trials. Second, it is unclear what the relative contribution of immunosuppression in the periphery versus the tumor microenvironment has on treatment resistance in recurrent glioblastomas. Therefore, they conclude that combination treatment, rather than single-agent monotherapy, will more likely affect meaningful clinical results.

Wong et al. (2014) analyzed the characteristics of responders and nonresponders in both cohorts of the phase III trial which compared NovoTTF-100A Best Physician's Choice (BPC) chemotherapy for recurrent glioblastoma to determine the characteristics of response and potential predictive factors. Their analysis showed that a significantly higher proportion of NovoTTF-100A responders, five of 14 (36%), had prior low-grade histologies while none of seven (0%) BPC responder had this type of histological characteristics, suggesting that secondary glioblastoma may be more responsive to NovoTTF-100A treatment. Because primary and secondary glioblastomas have different genetic alterations, notably *EGFR* and *MDM2* amplifications together with *p16* deletion in primary glioblastomas and mutation, *IDH1* mutation and *PDGFR* amplification in secondary glioblastomas, the distinct genetic makeup in these two subtypes of glioblastomas could make secondary glioblastomas more susceptible to NovoTTF-100A treatment. Secondary glioblastomas and low dexamethasone usage are associated with a higher proportion of NovoTTF-100A responders but not BPC chemotherapy responders. The authors surmise that during treatment with NovoTTF-100A, this slower rate of tumor progression might allow enough time for the efficacy of TTF fields to emerge because it may take multiple mitotic cycles to reduce the number of tumor cells and the size of the glioblastoma. The authors recommend that future clinical trials on the NovoTTF-100A device must include stratification of potential predictive factors of response that include both genetic and epigenetic determinants.

Mrugala et al. (2014) evaluated data collected from all adult patients with recurrent GBM who began commercial Novocure TTF therapy through the Patient Registry Dataset (PRiDe), which is a post-marketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in the United States between 2011 and 2013. Data from 457 recurrent GBM patients who received Novocure TTF therapy in 91 US cancer centers were analyzed. More patients in PRiDe than the EF-11 trial received Novocure TTF therapy for first recurrence (33% v 9%) and had received prior bevacizumab therapy (55.1% v 19%). Median OS was significantly longer with Novocure TTF therapy in clinical practice (PRiDe data set) than in the EF-11 trial (9.6 v 6.6 months; HR, 0.66; 95% CI, 0.05 to 0.86,  $P = .0003$ ). One- and 2-year OS rates were more than double for Novocure TTF therapy patients in PRiDe than in the EF-11 trial (1-year: 44% v 20%; 2-year: 30% v 9%). First and second versus third and subsequent recurrences, high Karnofsky performance status (KPS), and no prior bevacizumab use were favorable prognostic factors. No unexpected adverse events were detected in PRiDe. As in the EF-11 trial, the most frequent adverse events were mild to moderate skin reactions associated with application of the Novocure TTF therapy transducer arrays. The authors concluded that results from PRiDe, together with those previously reported in the EF-11 trial, indicate that Novocure TTF therapy offers clinical benefit to patients with recurrent GBM, has high patient tolerability and favorable safety profile in the real-world, clinical practice setting.

Rulseh et al. (2012) reported the long-term survival of patients with glioblastoma multiforme treated with tumor-treating fields in a small pilot study of 20 individuals. The inclusion criteria of the study included a KPS  $\geq 70\%$  and age  $\geq 18$  years, and the patients were divided into two groups. The first group consisted of 10 patients diagnosed with recurring GBM after failing temozolomide treatment that were treated with TTF field therapy alone, and the second group consisted of 10 newly diagnosed GBM patients at least four weeks post radiation therapy (with adjuvant temozolomide) that received TTF field therapy combined with maintenance temozolomide. The treatment duration in individual patients varied between one and one and a half years, and all histological samples were independently examined in two laboratories in two countries. Twenty percent of the participants in the pilot study (4 out of 20) survived until the time of their report, roughly seven years. The individuals showed no clinical or radiological signs of recurrence and were no longer receiving any treatment. The authors suggest that in order to increase the probability of response to TTF field therapy and subsequent long term survival, TTF field treatment should be continued even in the face of initial radiologic tumor growth.

There is a lack of published evidence from randomized controlled trials examining the long-term safety and effectiveness of TTF as a treatment for tumors other than GBM, including non-small cell lung, brain metastasis, pancreatic cancer, ovarian cancer and mesothelioma.

### **NovoTAL™ Simulation System**

There is limited published clinical evidence related to the NovoTAL™ simulation system, and insufficient data to support improved long-term health outcomes with its use. This includes a small case series (Connelly et al., 2016), human head model (Wenger et al., 2015), and a user group survey (Chaudry et al., 2015). A framework for the use of NovoTAL in treatment planning has been proposed by Trusheim et al. (2016).

## U.S. FOOD AND DRUG ADMINISTRATION (FDA)

The Optune is categorized by the FDA as a stimulator, low electric field, tumor treatment; see the following website for the initial Premarket Approval information: <https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm?id=P100034S013>. (Accessed November 09, 2018)

Refer to the following website for additional information on supplemental FDA approvals for the Optune using product code NZK: <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm>. (Accessed November 09, 2018)

NovoTAL simulation software is not regulated by the FDA.

## CENTERS FOR MEDICARE AND MEDICAID SERVICES (CMS)

Medicare does not have a National Coverage Determination (NCD) for electric tumor treatment field therapy. Local Coverage Determinations (LCDs) exist, see the LCDs for Tumor Treatment Field Therapy (TTFT). (Accessed November 09, 2018)

#### INSTRUCTIONS FOR USE

This Medical Policy provides assistance in interpreting UnitedHealthcare standard benefit plans. When deciding coverage, the member specific benefit plan document must be referenced as the terms of the member specific benefit plan may differ from the standard plan. In the event of a conflict, the member specific benefit plan document governs. Before using this policy, please check the member specific benefit plan document and any applicable federal or state mandates. UnitedHealthcare reserves the right to modify its Policies and Guidelines as necessary. This Medical Policy is provided for informational purposes. It does not constitute medical advice.

UnitedHealthcare may also use tools developed by third parties, such as the MCG™ Care Guidelines, to assist us in administering health benefits. UnitedHealthcare Medical Policies are intended to be used in connection with the independent professional medical judgment of a qualified health care provider and do not constitute the practice of medicine or medical advice.

## ***Tumor Treating Fields Therapy for Glioblastoma***

**Effective:** May 1, 2018

**Next Review:** February 201

**Last Review:** March 2018

### **IMPORTANT REMINDER**

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

### **DESCRIPTION**

Glioblastoma multiforme is the most common and deadly form of malignant brain tumor in adults. It has a very poor prognosis and is associated with low quality of life during the course of treatment. Tumor treating fields therapy is a new, noninvasive technology that is intended to treat glioblastoma using electrical fields.

### **MEDICAL POLICY CRITERIA**

- I. Tumor treating fields (TTF) to treat primary supratentorial glioblastoma multiforme (GBM) may be considered **medically necessary** when all of the following are met:
  - A. Patient is 18 years of age or older; and
  - B. Documentation of histologically-confirmed primary supratentorial GBM; and
  - C. Following radiation and chemotherapy; and
  - D. Concurrent treatment with temozolomide (TMZ), unless TMZ has been ineffective, not tolerated, or is contraindicated.
- II. The use of mapping software to optimize TTF therapy may be considered **medically necessary** for GBM when patients meet criterion I. above.
- III. The use of TTF and/or TTF-associated mapping software is considered

**investigational** when the above criterion I. is not met.

*NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.*

## POLICY GUIDELINES

It is critical that the list of information below is submitted for review to determine if the policy criteria are met. If any of these items are not submitted, it could impact our review and decision outcome.

- History and Physical/Chart Notes
- Documentation of histologically-confirmed primary supratentorial glioblastoma multiforme (GBM)
- Radiation and chemotherapy history
- Documentation of Temozolomide (TMZ) maintenance treatment and response

## CROSS REFERENCES

## BACKGROUND

Glioblastoma multiforme (GBM) are the most common and deadly malignant brain tumor. Glioblastoma is the most common malignant primary brain tumor in adults, with a median age at diagnosis of 64 years.<sup>[1]</sup> GBMs are grade IV astrocytomas, the most deadly type of glial cell tumor, and are often resistant to standard chemotherapy. According to the National Comprehensive Cancer Network (NCCN), GBM is the "deadliest brain tumor with only a third of patients surviving for 1 year and less than 5% living beyond 5 years."<sup>[2]</sup>

The primary treatment for GBM is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine bis chloroethylnitrosourea (BCNU)-impregnated wafer.<sup>[2]</sup> Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide [TMZ]), or a combination of the two are sometimes given. After adjuvant therapy, some patients may undergo maintenance therapy with TMZ. In patients with disease that recurs after these initial therapies, additional debulking surgery may be used if recurrence is localized. Treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, BCNU/chloroethylnitrosourea (CCNU), TMZ), TMZ, nitrosourea, PCV (procarbazine, CCNU, and vincristine), cyclophosphamide, and platinum-based agents.<sup>[2]</sup> Response rates in recurrent disease are less than 10%, and progression-free survival rates at 6 months are less than 20%.<sup>[2,3]</sup>

## TUMOR TREATING FIELDS THERAPY

Tumor Treating fields (TTF) therapy is a new, noninvasive technology that is intended to treat GBM on an outpatient basis using electrical fields.<sup>[3-5]</sup> TTF therapy exposes cancer cells to alternating electric fields of low intensity and intermediate frequency, which are purported to both selectively inhibit tumor growth and reduce tumor angiogenesis. TTF are proposed to inhibit rapidly dividing tumor cells by 2 mechanisms, arrest of cell proliferation and destruction of cells while undergoing division.<sup>[4,5]</sup>

The Optune™, formerly known as NovoTTF-100A™ System, (Novocure Inc.) has been approved by the U.S. Food and Drug Administration (FDA) to deliver TTF therapy. TTF therapy via the Optune™ is delivered by a battery-powered, portable device that generates the fields via disposable electrodes that are noninvasively attached to the patient's shaved scalp over the site of the tumor.<sup>[3,4]</sup> The device is used by the patient at home on a continuous basis (20-24 hours per day) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.<sup>[3,4]</sup>

## **NOVOTAL™ SYSTEM**

The NovoTAL™ (Transducer Array Layout) System (Novocure Inc.) is a proprietary software tool that produces a custom transducer array layout to optimize Optune therapy for each patient. The software accomplishes this by maximizing the intensity of Tumor Treating Fields (TTFields) based on MRI measurements of the head, tumor size and location(s) and optimizing TTFields distribution.

## **REGULATORY STATUS**

Optune™, (assigned the generic name of TTF) was approved by Food & Drug Administration (FDA) in April 2011 through the premarket approval (PMA) process.<sup>[6]</sup> FDA-approved indication for use are:

“Optune™ is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM).

Optune™ with temozolomide (TMZ), is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy. (FDA PMA approval granted in October 2015)

For the treatment of recurrent GBM, Optune™ is indicated following histologically- or radiologically-confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.”<sup>[7]</sup>

The NovoTAL™ System, was approved by the FDA in November 2013 through a PMA supplement for the Optune™ System. It is the software approved for use by physicians certified to prescribe the Optune™ System.

## **EVIDENCE SUMMARY**

### **PRIMARY GLIOBLASTOMA MULTIFORME**

In 2015, Stupp published interim results of a randomized controlled trial (RCT) regarding the safety and efficacy of TTF used in combination with temozolomide maintenance treatment after chemoradiation therapy for patients with GBM.<sup>[8]</sup> Patients were randomized in a 2:1 fashion to receive maintenance treatment with TTF and TMZ (n=466) or TMZ only (n=229). Study eligibility required patients to be 18 years or older, have a histologically confirmed supratentorial glioblastoma, be progression-free after having undergone maximal safe debulking surgery when feasible or biopsy, and have completed standard concomitant

chemoradiotherapy with TMZ. The median time from diagnosis to randomization was 3.8 months in both groups and patients were not blinded due to ethical concerns. TTF was delivered continuously (> 18 hours/day) via 4 transducers placed on the shaved scalp and TMZ (150-200 mg/m<sup>2</sup>/d) was given for 5 days of each 28-day cycle. Transducer array layouts were determined using the NvoTAL mapping software system for TTF fields to optimize field intensity within the treated tumor. A planned interim analysis was to be conducted on the first 315 patients at 18 months follow-up. The primary study endpoint was progression-free survival (PFS) in the intent-to-treat populations (with a significance threshold of .01) with overall survival (OS) in the per-protocol population (n = 280) as a powered secondary endpoint (significance threshold of .006). A total of 695 patients were enrolled across 83 centers; however the trial was terminated as it met its efficacy endpoints at interim analysis (median 38 months, 315 patients).

The interim analysis included the planned 315 subjects, with 210 in the TTF/TMZ group and 105 in the TMZ only group. The analysis was conducted at a median 38 months follow-up (range, 18-60 months). Prespecified per-protocol median PFS in the TTF/TMZ group was 7.1 months (95% CI, 5.9-8.2 months) compared to 4 months (95% CI, 3.3-5.2 months) in the TMZ only group (hazard ratio [HR], 0.62 [98.7% CI, 0.43-0.89]; P = .001). The median OS in the per-protocol population was statistically improved in the TTF/TMZ group (20.5 months; 95% CI, 16.7-25.0 months) compared to the TMZ only group (15.6 months; 95% CI, 13.3-19.1 months; HR, 0.64 [99.4% CI, 0.42-0.98]; P = .004). An additional analysis of the intention-to-treat population demonstrated and OS of 19.6 months (95% CI, 16.6-24.4 months) in the TTF/TMZ group compared to 16.6 months (95% CI, 13.6-19.2 months) in the TMZ only group (HR, 0.74 [95% CI, 0.56-0.98]; stratified log-rank p = .03). Forty-three percent of patients in the TTF/TMZ group were alive at 2-year follow-up, compared to 29% in the TMZ only group (p = .006).

These interim results demonstrate an approximate three-month improvement of PFS and five-month improvement of OS when TTF therapy is used concurrently with TMZ in patients with newly diagnosed GBM.

In 2017, Stupp published final results from this trial, including all 695 subjects.<sup>[9]</sup> From the time of randomization, median progression-free survival was 6.7 months in the TTF/TMZ group, and 4.0 months in the TMZ only group (HR, 0.63; 95% CI, 0.52-0.76; P < .001). Median overall survival was 20.9 months in the TTF/TMZ group as compared to 16.0 months in the TMZ only group (HR, 0.63; 95% CI, 0.53-0.76; P < .001). The application of TTF therapy in addition to TMZ treatment compared to TMZ treatment alone was not associated with an increase in adverse events (48% vs 44%, P = 0.58). Mild to moderate skin irritation was observed in 52% of patients who received TTF/TMZ treatment.

## **RECURRENT GLIOBLASTOMA MULTIFORME**

The literature on the efficacy of TTF therapy in patients with recurrent GBM consists of small, single-arm studies and two RCTs.

### **Randomized Controlled Trials**

The use of TTF and the corresponding effects on living tissue have been studied in clinical settings.<sup>[10-12]</sup> For example, in 2007, Kirson, reported the findings of a case study examining the effects of TTF therapy delivered by the NovoTTF-100A System in 10 patients with recurrent GBM.<sup>[10]</sup> Median time to progression (TTP) in these patients was 26.1 weeks and

median overall survival (OS) was 62.2 weeks. The authors noted that these TTP and OS values were more than double the reported medians of historical control patients. No device-related serious adverse events were seen after more than 70 months of cumulative treatment in all of the patients. The only device-related adverse event observed was a mild-to-moderate contact dermatitis beneath the field delivering electrodes. The primary limitation of this study was the use of historical controls, since the patients included may not be comparable on major clinical and prognostic features.<sup>[10]</sup>

These preliminary findings served as a basis for a 2012 prospective Phase III multinational RCT by Stupp, which was sponsored and funded by the manufacturer of the device (NovoCure). This study compared TTF therapy (delivered by the NovoTTF-100A System) to the best standard of care chemotherapy (active control).<sup>[3]</sup> Twenty-eight clinical centers (across 7 countries) enrolled 237 adult participants with relapsed or progressive GBM, despite conventional radiotherapy. Other prior treatments may have included surgery and/or chemotherapy. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky performance status (KPS) of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens ( $\geq$  second recurrence), and 20% had failed bevacizumab prior to study enrollment.<sup>[3]</sup>

Two hundred thirty-seven patients were randomized in a 1:1 ratio to receive TTF therapy only (n=120) or active control (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the participating clinical centers.<sup>[3]</sup> Chemotherapy agents considered as active control during the trial included platinum-based chemotherapy (i.e., carboplatin); nitrosureas; procarbazine; combination of procarbazine, lomustine and vincristine (PCV); temozolomide; and bevacizumab. For patients assigned to the TTF group, uninterrupted treatment was recommended, although patients were allowed to take treatment breaks of up to 1 hour, twice per day, for personal needs (e.g., shower). In addition, patients assigned to the TTF group were allowed to take 2 to 3 days off treatment at the end of each of 4-week period (which is the minimal required treatment duration for TTF therapy to reverse tumor growth). A period of 28 days of treatment with TTF was considered 1 full treatment course.<sup>[3]</sup>

The primary study end point in this RCT was OS.<sup>[3]</sup> Secondary end points included progression-free survival (PFS) at 6 months, total time to progression (TTP), 1-year survival rate, quality of life (QOL), and radiological response. Participants were seen in clinic monthly, and magnetic resonance imaging (MRI) was performed after 2, 4, and 6 months from initiation of treatment, with subsequent MRIs done according to local practice until disease progression. Medical follow-up continued for 2 months after disease progression. Monthly telephone interviews with the participants' caregivers were used to assess participant mortality rates.<sup>[3]</sup>

Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device.<sup>[3]</sup> For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available.<sup>[3]</sup>

This RCT did not reach its primary end point of improved survival compared to active

chemotherapy.<sup>[3]</sup> With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared to 6.0 months in the active control group (hazard ratio, 0.86; 95% confidence interval [CI], 0.66 to 1.12;  $p=0.27$ ). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared to 15.1% in the active control group ( $p=0.13$ ). Objective radiological responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) compared to 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents utilized; severe (grades 3 and 4) toxicity was observed in 3% of participants.<sup>[3]</sup>

Longitudinal QOL data were available in 63 participants (27%).<sup>[3]</sup> There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group.

In summary, this RCT failed to demonstrate the primary end point of improved survival with TTF therapy in comparison to chemotherapy.<sup>[3,13]</sup> Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of 1 or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or of TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy.

A further limitation was high dropout rates in both groups. For example, over 20% of participants in the active control group were lost at follow-up, and this may have underestimated the toxicity evaluation in this group. Similarly, over 20% of participants in the TTF arm discontinued treatment within a few days due to noncompliance or inability to handle the device. This implies that compliance might be an issue with TTF, as it requires the patient to continuously wear transducers on the shaved head. Finally, the number of patients who completed the QOL data was approximately one-quarter of total enrollment, and the self-reported QOL indicators may have been subject to bias due to the lack of blinding.<sup>[3,6]</sup> Therefore, due to the numerous methodologic limitations, evidence from this trial is not sufficient to demonstrate that TTF therapy results in improved health outcomes for patients with recurrent GBM.

Post hoc subgroup analyses of these trial data have been published in abstract form comparing outcomes of patients between both groups who had failed bevacizumab prior to

study enrollment.<sup>[14,15]</sup> For example, Wong et al., published a subgroup analysis of the previously described RCT to determine characteristics of responders and nonresponders in the treatment and active control groups.<sup>[16]</sup> Tumor response was assessed by the Macdonald criteria. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p < 0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p < 0.001$ ) but not in chemotherapy arm ( $p = 0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

## **Nonrandomized Studies**

A study published in late 2014 included OS data from 457 patients included in the Patient Registry Dataset (PRiDe), a postmarketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in 91 centers.<sup>[17]</sup> The median OS rate in the PRiDe clinical practice dataset was reported as significantly superior to that attained in the TTF pivotal trial (9.6 months vs 6.6 months; HR=0.66, 95% CI, 0.05 to 0.86;  $p < 0.001$ ). One- and 2-year OS rates for TTF in PRiDe were significantly longer than those in the TTF group in the pivotal RCT (44% vs 20% at 1 year; 30% vs 9% at 2 years, respectively). The PRiDe investigators reported no novel or unexpected treatment-related adverse events compared with the pivotal RCT. These results, although promising, are limited by a lack of randomized comparison group with which to isolate the direct effect of TTF therapy upon symptom improvement and overall outcomes.

In addition, two very small case series have also been published of long-term survival (>6 years) with TTF therapy.<sup>[18,19]</sup> Since the approval of the NovoTTF device, additional case reports and very small case series ( $n=3-5$ ) have been reported.<sup>[20-22]</sup>

## **NOVOTAL™ SYSTEM**

### **Nonrandomized Studies**

In 2016, Connelly published a small feasibility study using the NovoTAL™ System with nonstandard non-contrast enhancement and advanced imaging.<sup>[23]</sup> All patients presented with gliomas (grades 2-4) and had previously received standard therapy prior to initiation of TTFields. A standard pre- and postcontrast MRI scan was acquired and used for TTFields treatment planning, in conjunction with other imaging modalities. Eight patients were reported on in this series: three underwent T2 imaging, one underwent FLAIR, one used diffusion weighted imaging, and one used MR-perfusion imaging. This case series demonstrates that treatment planning beyond the extent of contrast enhanced MRI is clinically feasible but it must be prospectively compared to standard treatment planning in a clinical trial setting, in order to determine the impact on patient outcomes.

In 2015, Chaudhry et al. evaluated physician performance in conducting transducer array layout mapping using the NovoTAL™ System compared with mapping performed by the Novocure in-house clinical team.<sup>[24]</sup> Fourteen physicians (seven neuro-oncologists, four medical oncologists, and three neurosurgeons) evaluated five blinded cases of recurrent glioblastoma. Concordance for each physician versus Novocure on 20 MRI measurements

was 0.96 (standard deviation, SD  $\pm$  0.03, range 0.90-1.00), indicating very high agreement between the two groups, indicating that physicians prescribing TTFields, when trained on the NovoTAL™ System, can independently perform transducer array layout mapping required for the initiation and maintenance of patients on TTFields therapy. This study did not address clinical utility.

## PRACTICE GUIDELINE SUMMARY

### NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN) clinical practice guidelines on Central Nervous Systems Tumors (v.1.2017) recommend TTF therapy in conjunction with standard brain radiation therapy and current/adjuvant temozolomide for patients with supratentorial disease with good performance status. This is a category 3 recommendation. The panel conceded that data regarding TTF therapy is limited to evidence from the Stupp RCT which demonstrated similar survival in between groups. In addition, in the background section, the panel indicated that TTF therapy may be considered as a treatment option for recurrent GBM but not all panelists recommend treatment for these patients due to a lack of efficacy. The NCCN guideline does not address the use of TTF therapy recommendation section for patients with recurrent disease.<sup>[2]</sup>

## SUMMARY

The research on the safety and efficacy of tumor treating fields (TTF) therapy for patients with primary glioblastoma has some limitations. However, the small number of studies published do show that TTF therapy improves progression-free and overall survival in adult patients with primary glioblastoma multiforme (GBM) who are receiving concurrent temozolomide (TMZ) treatment. Therefore, TTF therapy may be considered medically necessary when criteria are met. TTF therapy in patients with recurrent glioblastoma multiforme (GBM) is limited to one randomized controlled trial which failed to demonstrate an improvement in overall survival or disease response. Due to insufficient research, the use of TTF therapy is considered investigational when criteria are not met, including but not limited to patients with recurrent glioblastoma.

There is limited research to show that the use of software to optimize tumor treating fields (TTF) therapy (e.g., the NovoTAL™ System) when used in conjunction with TTF therapy improves the outcomes of patients with glioblastoma compared to patients treated with TTF therapy alone. Despite these limitations, the use software to optimize TTF therapy in patients with glioblastoma may be medically necessary when criteria are met. Due to insufficient research, the use of TTF-associated mapping software is considered investigational when criteria are not met.

## CODES

**NOTE:** There is no specific code for the NovoTAL System software program. While some may submit using CPT code 77261, the appropriate CPT code for this service is unlisted code 77299.

Codes	Number	Description
CPT	77261	Therapeutic radiology treatment planning; simple
	77299	Unlisted procedure, therapeutic radiology clinical treatment planning
HCPCS	A4555	Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only
	E0766	Electrical stimulation device, used for cancer treatment, includes all accessories, any type

**Date of Origin:** January 2014

## Medical Necessity Guidelines: Tumor Treating Fields (TTF)

Effective: December 13, 2017

Clinical Documentation and Prior Authorization Required	✓	Coverage Guideline, No Prior Authorization	
Applies to: <input checked="" type="checkbox"/> Tufts Health Plan Commercial Plans products; Fax: 617.972.9409 <input checked="" type="checkbox"/> Tufts Health Public Plans products <input checked="" type="checkbox"/> Tufts Health Direct – Health Connector; Fax: 888.415.9055 <input checked="" type="checkbox"/> Tufts Health Together – A MassHealth Plan; Fax: 888.415.9055 <input type="checkbox"/> Tufts Health Unify – OneCare Plan; Fax: 781.393.2607 <input checked="" type="checkbox"/> Tufts Health RITogether – A Rhode Island Medicaid Plan; Fax: 857.304.6404 <input checked="" type="checkbox"/> Tufts Health Freedom Plan products; Fax: 617.972.9409			

**Note:** While you may not be the provider responsible for obtaining prior authorization, as a condition of payment you will need to make sure that prior authorization has been obtained.

### OVERVIEW

Glioblastomas (grade IV astrocytomas) are one of the most common types of primary malignant brain tumors in adults. These tumors develop from glial cells in the brain and are usually highly malignant (cancerous) because the cells reproduce quickly and they are supported by a large network of blood vessels. Virtually all patients with newly diagnosed GBM relapse despite best available treatment. At the time of disease recurrence, treatment options for GBM patients are limited. Tumor treating fields (TTF) therapy is administered via a portable medical device that generates low-intensity alternating electric fields, called tumor treating fields. TTF aims to treat recurrent GBM by disrupting the rapid cell division exhibited by malignant cells.

### COVERAGE GUIDELINES

Tufts Health Plan may authorize coverage of TTF therapy as monotherapy in adult patients (22 years of age and older) with histologically-or radiologically-confirmed **recurrent** glioblastoma (GBM) after surgical and radiation options have been exhausted.

### LIMITATIONS

Tufts Health Plan will not cover TTF therapy for the treatment of any condition not outlined above.

### CODES

The following HCPCS code(s) require prior authorization:

**Table 1: HCPCS Codes**

CPT Code	Description
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type
A4555	Electrode/transducer for use with electrical stimulation device used for cancer treatment, replacement only

**Table 3: ICD-10 Codes**

ICD-10 Code	Description
C71.0	Malignant neoplasm of cerebrum, except lobes and ventricles
C71.1	Malignant neoplasm of frontal lobe
C71.2	Malignant neoplasm of temporal lobe
C71.3	Malignant neoplasm of parietal lobe
C71.4	Malignant neoplasm of occipital lobe

ICD-10 Code	Description
C71.5	Malignant neoplasm of cerebral ventricle
C71.6	Malignant neoplasm of cerebellum
C71.7	Malignant neoplasm of brain stem
C71.8	Malignant neoplasm of overlapping sites of brain
C71.9	Malignant neoplasm of brain, unspecified

## APPROVAL HISTORY

August 10, 2016: Reviewed by the Integrated Medical Policy Advisory Committee (IMPAC), effective January 1, 2017.

Subsequent endorsement date(s) and changes made:

- November 9, 2016: Reviewed by IMPAC, renewed without changes
- February 8, 2017: Reviewed by IMPAC, renewed without changes
- April 2017: Added RITogether Plan product to template. For MNGs applicable to RITogether, effective date is August 1, 2017
- December 13, 2017: Reviewed by IMPAC, renewed without changes

## BACKGROUND, PRODUCT AND DISCLAIMER INFORMATION

Medical Necessity Guidelines are developed to determine coverage for benefits, and are published to provide a better understanding of the basis upon which coverage decisions are made. We make coverage decisions using these guidelines, along with the Member's benefit document, and in coordination with the Member's physician(s) on a case-by-case basis considering the individual Member's health care needs.

Medical Necessity Guidelines are developed for selected therapeutic or diagnostic services found to be safe and proven effective in a limited, defined population of patients or clinical circumstances. They include concise clinical coverage criteria based on current literature review, consultation with practicing physicians in our service area who are medical experts in the particular field, FDA and other government agency policies, and standards adopted by national accreditation organizations. We revise and update Medical Necessity Guidelines annually, or more frequently if new evidence becomes available that suggests needed revisions.

Medical Necessity Guidelines apply to the fully insured Commercial and Medicaid products when Tufts Health Plan conducts utilization review unless otherwise noted in this guideline or in the Member's benefit document, and may apply to Tufts Health Unify to the same extent as Tufts Health Together. This guideline does not apply to Tufts Medicare Preferred HMO, Tufts Health Plan Senior Care Options or to certain delegated service arrangements. For self-insured plans, coverage may vary depending on the terms of the benefit document. If a discrepancy exists between a Medical Necessity Guideline and a self-insured Member's benefit document, the provisions of the benefit document will govern. Applicable state or federal mandates or other requirements will take precedence. For CareLink<sup>SM</sup> Members, Cigna conducts utilization review so Cigna's medical necessity guidelines, rather than these guidelines, will apply.

Treating providers are solely responsible for the medical advice and treatment of Members. The use of this guideline is not a guarantee of payment or a final prediction of how specific claim(s) will be adjudicated. Claims payment is subject to eligibility and benefits on the date of service, coordination of benefits, referral/authorization, utilization management guidelines when applicable, and adherence to plan policies, plan procedures, and claims editing logic.

### INSTRUCTIONS FOR USE

This Medical Policy provides assistance in interpreting UnitedHealthcare benefit plans. When deciding coverage, the federal, state or contractual requirements for benefit plan coverage must be referenced. The terms of the federal, state or contractual requirements for benefit plan coverage may differ greatly from the standard benefit plan upon which this Medical Policy is based. In the event of a conflict, the federal, state or contractual requirements for benefit plan coverage supersede this Medical Policy. All reviewers must first identify member eligibility, any federal or state regulatory requirements, and the contractual requirements for benefit plan coverage prior to use of this Medical Policy. Other Policies and Coverage Determination Guidelines may apply. UnitedHealthcare reserves the right, in its sole discretion, to modify its Policies and Guidelines as necessary. This Medical Policy is provided for informational purposes. It does not constitute medical advice.

UnitedHealthcare may also use tools developed by third parties, such as the MCG™ Care Guidelines, to assist us in administering health benefits. The MCG™ Care Guidelines are intended to be used in connection with the independent professional medical judgment of a qualified health care provider and do not constitute the practice of medicine or medical advice.

### BENEFIT CONSIDERATIONS

Before using this policy, please check the federal, state or contractual requirements for benefit coverage.

### COVERAGE RATIONALE

**The use of U.S. Food and Drug Administration (FDA) approved devices to generate electric tumor treatment fields (TTF) to treat histologically-confirmed Supratentorial glioblastoma (known also as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) is proven and medically necessary as adjunctive therapy when used according to FDA labeled indications, contraindications, warnings and precautions, and when ALL of the following criteria are met:**

- Initial treatment with debulking surgery or biopsy followed by chemoradiation with concomitant Temozolomide and radiotherapy has been completed; and
- Individual has Karnofsky Performance Status (KPS) score of >60; and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

When all of the above criteria are met, an initial 3 months of electric TTF therapy will be approved.

Subsequent approval(s) for continuation of electric TTF is based on:

- Evidence of no documented disease progression by magnetic resonance imaging (MRI) done at a minimum of every 2-4 months. This includes a completed MRI scan with report submitted as part of any request for continuation of electric TTF treatment; and

- KPS score of >60; and
- Documentation that the individual and/or caregiver have been applying the device daily; and
- Documentation that the patient has been wearing the device at least 18 hours daily.

**The use of devices to generate electric tumor treatment fields (TTF) is considered investigational, unproven, and not medically necessary when the criteria above are not met and for all other indications.** The FDA has not approved the use of electric TTF devices for indications other than GBM. Further studies are needed to determine the safety and long-term efficacy of electric TTF therapy for other types of cancer.

**Computer software used for therapeutic radiology clinical treatment planning in conjunction with electric tumor treatment field (TTF) therapy is unproven and not medically necessary.** There is insufficient evidence to establish the efficacy of these products in the long-term outcomes of patients receiving electric TTF therapy.

## DEFINITIONS

Please check the definitions within the member benefit plan document that supersede the definitions below.

**Karnofsky Performance Status (KPS):** A standard way of measuring the ability of cancer patients to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities. For example, a KPS of 60 means a person requires occasional assistance, but is able to care for most of their personal needs. KPS may be used to determine a patient's prognosis, to measure changes in a patient's ability to function, or to decide if a patient could be included in a clinical trial.

**Supratentorial:** The upper portion of the brain comprised of the cerebrum and the diencephalon.

**Temozolomide:** An oral alkylating chemotherapy drug used in the treatment of some brain cancers. It is a first-line treatment for glioblastoma.

## APPLICABLE CODES

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by federal, state or contractual requirements and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies and Coverage Determination Guidelines may apply.

CPT Code	Description
77299	Unlisted procedure, therapeutic radiology clinical treatment planning <i>CPT® is a registered trademark of the American Medical Association</i>
HCPCS Code	Description
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type

## DESCRIPTION OF SERVICES

Electric tumor treatment field (TTF) therapy (also known as tumor-treating fields, TTFields, ETTFs) is based on the principle that low intensity, intermediate frequency electric fields (100 to 300 kHz) have an anti-mitotic effect which acts during late metaphase and anaphase, with specific frequencies affecting specific cell types (Rulseh et al, 2012).

Alternating electrical fields within the human body that disrupt the rapid cell division exhibited by cancer cells, with the alternating electrical fields applied to the brain through transducer arrays placed on the scalp. TTF harness electric fields to arrest the proliferation of tumor cells and to destroy them. The TTF technology takes advantage of the special characteristics and geometrical shape of dividing cells, which make them susceptible to the effects of the alternating electric TTFields. These special fields alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used for a particular treatment is specific to the cell type being treated (e.g., 200kHz for GBM). In contrast, the TTFields have not been shown to have an effect on cells that are not undergoing division. Since most normal adult brain cells proliferate very slowly, if at all, they are hypothesized to be little affected by the TTFields. (Novocure, 2017)

Glioblastoma multiforme (GBM) is the most prevalent and primary malignant brain tumor in adults, accounting for 54% of all gliomas. GBM is the most lethal brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years. Unfortunately most glioblastomas recur (NCCN, 2016). It develops from star-shaped glial cells (astrocytes and oligodendrocytes) that support the health of the nerve cells within the brain.

The mainstay of treatment for GBM is surgery, followed by radiation and chemotherapy. The primary objective of surgery is to remove as much of the tumor as possible without injuring the surrounding healthy brain tissue needed for normal neurological function (such as motor skills, the ability to speak and walk, etc.). However, GBMs are surrounded by a zone of migrating, infiltrating tumor cells that invade surrounding tissues, making it impossible to ever remove the tumor entirely. Surgery provides the ability to reduce the amount of solid tumor tissue within the brain, remove those cells in the center of the tumor that may be resistant to radiation and/or chemotherapy and reduce intracranial pressure. [American Association of Neurological Surgeons (AANS), 2015]

The Optune<sup>®</sup>, formerly the NovoTTF-100A System, (Novocure, Portsmouth NH) was approved by the FDA in April 2011, as a novel device to treat adults age 22 years or older with GBM that recurs or progresses after receiving chemotherapy and radiation therapy.

A supplemental FDA premarket approval was received in October 2015 for Optune<sup>™</sup> with Temozolomide in adult patients with newly diagnosed, Supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy. For newly diagnosed GBM, Optune is not intended to be used as a substitute for standard treatments but rather as an adjunct therapy.

Refer to the [U.S. Food and Drug Administration \(FDA\)](#) section for additional information.

The Optune kit contains the portable electric field generator (Optune device), INE (insulated electrode) transducer arrays, power supply, and additional supplies. Prior to treatment, transducer arrays are placed on the patient's scalp according to the tumor's location, which are then covered by a lightweight white cap which resembles a bandage. The patient receives the noninvasive TTF treatment for at least 18 continuous hours per day for a minimum of 4 weeks. As the Optune device is portable, patients are able to carry out every-day activities.

Treatment parameters are preset by the manufacturer such that there are no electrical output adjustments available to the patient. The patient or caregiver must learn to change and recharge depleted device batteries and to connect to an external power supply overnight. In addition, the transducer arrays need to be replaced once to twice a week and the scalp re-shaved in order to maintain optimal contact.

The NovoTAL<sup>™</sup> (transducer array layout) system is optional simulation software for use in clinical treatment planning with Optune therapy that may be leased from the manufacturer. Its purpose is to determine the optimal location of the transducer arrays based on the patient's most recent magnetic resonance imaging (MRI) scan, head size, and tumor location.

TTF technology is also being studied through ongoing clinical trials as a treatment for other solid tumors such as non-small cell lung cancer, brain metastasis, pancreatic cancer, ovarian cancer and mesothelioma.

## CLINICAL EVIDENCE

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guideline for Central Nervous System Cancers, anaplastic gliomas/glioblastoma GLIO-3 and GLIO-4, includes standard brain radiation therapy (RT) + concurrent temozolomide and adjuvant temozolomide + alternating electric field therapy for patients with good performance status and either methylated or unmethylated/indeterminate MGMT promoter status, with the following footnote: "Alternating electric field therapy is only an option for patients with supratentorial disease" (category 2A). For recurrence of GBM (GLIO-5), the guideline includes consideration of alternating electric treatment fields for glioblastoma after surgery, radiation and chemotherapy (category 2B) (NCCN, 2016).

In a multinational, open-label, randomized phase III trial (EF-14 trial), Stupp et al. (2015) compared Optune in combination with temozolomide to temozolomide alone in 700 patients age 18 and over with newly diagnosed GBM. The interim report revealed that in the intent-to-treat population, patients treated with TTFields plus temozolomide showed a statistically significant increase in progression free survival (PFS), the primary endpoint, compared to temozolomide alone (median PFS 7.1 months versus 4.0 months, hazard ratio=0.62, p=0.0013). In the per-protocol population, patients treated with TTFields plus temozolomide demonstrated a statistically significant increase in OS, a powered secondary endpoint, compared to temozolomide alone (median OS 20.5 months versus 15.6 months, hazard ratio=0.64, p=0.0042). In the intent-to-treat population, the median OS was 19.6 months versus 16.6 months, respectively, hazard ratio=0.74 (p=0.0329). The two-year survival rate was 50 percent greater with TTFields plus temozolomide versus temozolomide alone: 43 percent versus 29 percent. The trial's independent data monitoring

committee concluded that the study met its endpoints at its pre-specified interim analysis of the first 315 patients with 18 months or more of follow-up. The committee recommended that the trial be terminated early for success and that all control patients be offered TTFields therapy even prior to progression. In addition, the authors reported that the trial showed Optune could be safely combined with temozolomide. There was no significant increase in systemic toxicities from Optune reported in combination with temozolomide versus temozolomide alone. The most common adverse reaction from Optune treatment was mild to moderate skin irritation, which according to the authors was easily managed, reversible and did not result in treatment discontinuation. This clinical trial has some important limitations. Patient enrollment occurred only after the end of radiochemotherapy, leading to some variation in the delivery of standard treatment of temozolomide and radiotherapy. Patients who had progressed early during radiochemotherapy were not eligible for randomization, thus excluding patients with very poor prognoses. There is likely reporting bias for second-line therapies after tumor progression because in the TTFields plus temozolomide group, TTFields were to be continued, and thus, more detailed treatment information has been tracked for this group.

Stupp et al. (2012) completed a phase III randomized trial (EF-11 trial) of chemotherapy-free treatment of Novo tumor treatment fields (TTF) (20-24h/day) versus active chemotherapy in the treatment of patients with recurrent glioblastoma. The primary end-point was improvement of overall survival. Patients (median age 54 years (range 23-80), Karnofsky performance status 80% (range 50-100) were randomized to TTF alone (n=120) or active chemotherapy control (n=117). Number of prior treatments was two (range 1-6). Median survival was 6.6 versus 6.0 months (hazard ratio 0.86 [95% CI 0.66-1.12]; p=0.27), 1-year survival rate was 20% and 20%, progression-free survival rate at 6 months was 21.4% and 15.1% (p=0.13), respectively in TTF and active control patients. Responses were more common in the TTF arm (14% versus 9.6%, p=0.19). The TTF-related adverse events were mild (14%) to moderate (2%) skin rash beneath the transducer arrays. Severe adverse events occurred in 6% and 16% (p=0.022) of patients treated with TTF and chemotherapy, respectively. Quality of life analyses favored TTF therapy in most domains. Although no improvement in overall survival was demonstrated, the authors conclude that the efficacy and activity with this chemotherapy-free treatment device appears comparable to chemotherapy regimens that are commonly used for recurrent glioblastoma and that toxicity and quality of life favored TTF.

A treatment-based analysis of data from the pivotal phase III trial of the NovoTTF-100A System™ versus best physician's choice (BPC) chemotherapy was conducted by Kanner et al. (2014) in patients with recurrent glioblastoma multiforme (GBM), with particular focus on efficacy in patients using NovoTTF therapy as intended. Median overall survival (OS) was compared for recurrent GBM patients receiving at least one full cycle of treatment with NovoTTF-100A System or BPC chemotherapy (modified intention-to-treat [mITT] population). The relationship between NovoTTF-100A System compliance and OS was evaluated in the ITT population. Kaplan-Meier analyses examined treatment-related differences in OS for various patient subgroups. Median OS was significantly higher in patients receiving ≥1 course of NovoTTF therapy versus BPC (7.7 v 5.9 months; hazard ratio, 0.69; 95% confidence interval [CI], 0.52-0.91; P = .0093). Median OS was also significantly higher in patients receiving NovoTTF therapy with a maximal monthly compliance rate ≥75% (≥18 hours daily) versus those with a <75% compliance rate (7.7 v 4.5 months; P = .042), and Kaplan-Meier analysis demonstrated a significant trend for improved median OS with higher compliance (P = .039). Additional post hoc analysis showed significantly higher median OS with NovoTTF therapy than with BPC for patients with prior low-grade glioma, tumor size ≥18 cm(2), Karnofsky performance status ≥80, and those who had previously failed bevacizumab therapy. This contrasts with the equivalent efficacy reported previously based on analysis of all randomized ITT subjects, including many who did not receive a full cycle of treatment. The authors summarized that results from the present study suggest that when used as intended, NovoTTF Therapy provides efficacy superior to that of chemotherapy in a heterogeneous population of patients with recurrent GBM. Post hoc analyses identified subgroups of patients who may be particularly good candidates for NovoTTF Therapy, pending further confirmatory studies.

Wong et al., (2015) conducted a retrospective chart review from a single institution on patients treated with NovoTTF-100A and bevacizumab between November 2011 and December 2013. The patients were segregated into two cohorts: (i) those treated with NovoTTF-100A and bevacizumab only and (ii) those treated with NovoTTF-100A, bevacizumab and TCCC. Response to treatment was measured according to the Response Assessment in Neuro-Oncology criteria. Progression-free survival (PFS) and OS were measured from the time of application of these treatments to death or last follow up. The cohort treated with NovoTTF-100A, bevacizumab, and TCCC (n = 3) did not differ significantly from the rest of the cohort treated with NovoTTF-100A and bevacizumab only (n = 34). Potential reasons for this include baseline clinical characteristics and dexamethasone use. The authors note limitations with this review to be the number of patients treated with NovoTTF-100A, bevacizumab, and TCCC is small and therefore they cannot recommend this combination as standard clinical practice. However, they commented that the findings in their patients are notable and it can serve as a basis for future clinical trials. Second, it is unclear what the relative contribution of immunosuppression in the periphery versus the tumor microenvironment has on treatment resistance in recurrent glioblastomas. Therefore, they conclude that combination treatment, rather than single-agent monotherapy, will more likely affect meaningful clinical results.

Wong et al., (2014) analyzed the characteristics of responders and nonresponders in both cohorts of the phase III trial which compared NovoTTF-100A Best Physician's Choice (BPC) chemotherapy for recurrent glioblastoma to determine the characteristics of response and potential predictive factors. Their analysis showed that a significantly higher proportion of NovoTTF-100A responders, five of 14 (36%), had prior low-grade histologies while none of seven (0%) BPC responder had this type of histological characteristics, suggesting that secondary glioblastoma may be more responsive to NovoTTF-100A treatment. Because primary and secondary glioblastomas have different genetic alterations, notably EGFR and MDM2 amplifications together with p16 deletion in primary glioblastomas and mutation, IDH1 mutation and PDGFR amplification in secondary glioblastomas, the distinct genetic makeup in these two subtypes of glioblastomas could make secondary glioblastomas more susceptible to NovoTTF-100A treatment. Secondary glioblastomas and low dexamethasone usage are associated with a higher proportion of NovoTTF-100A responders but not BPC chemotherapy responders. The authors surmise that during treatment with NovoTTF-100A, this slower rate of tumor progression might allow enough time for the efficacy of TTFields to emerge because it may take multiple mitotic cycles to reduce the number of tumor cells and the size of the glioblastoma. The authors recommend that future clinical trials on the NovoTTF-100A device must include stratification of potential predictive factors of response that include both genetic and epigenetic determinants.

Mrugala et al., (2014) evaluated data collected from all adult patients with recurrent GBM who began commercial Novocure TTF therapy through the Patient Registry Dataset (PRiDe), which is a post-marketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in the United States between 2011 and 2013. Data from 457 recurrent GBM patients who received Novocure TTF therapy in 91 US cancer centers were analyzed. More patients in PRiDe than the EF-11 trial received Novocure TTF therapy for first recurrence (33% v 9%) and had received prior bevacizumab therapy (55.1% v 19%). Median OS was significantly longer with Novocure TTF therapy in clinical practice (PRiDe data set) than in the EF-11 trial (9.6 v 6.6 months; HR, 0.66; 95% CI, 0.05 to 0.86, P = .0003). One- and 2-year OS rates were more than double for Novocure TTF therapy patients in PRiDe than in the EF-11 trial (1-year: 44% v 20%; 2-year: 30% v 9%). First and second versus third and subsequent recurrences, high Karnofsky performance status (KPS), and no prior bevacizumab use were favorable prognostic factors. No unexpected adverse events were detected in PRiDe. As in the EF-11 trial, the most frequent adverse events were mild to moderate skin reactions associated with application of the Novocure TTF therapy transducer arrays. The authors concluded that results from PRiDe, together with those previously reported in the EF-11 trial, indicate that Novocure TTF therapy offers clinical benefit to patients with recurrent GBM, has high patient tolerability and favorable safety profile in the real-world, clinical practice setting.

Rulseh et al., (2012) reported the long-term survival of patients with glioblastoma multiforme treated with tumor-treating fields in a small pilot study of 20 individuals. The inclusion criteria of the study included a KPS  $\geq 70\%$  and age  $\geq 18$  years, and the patients were divided into two groups. The first group consisted of 10 patients diagnosed with recurring GBM after failing temozolomide treatment that were treated with TTField therapy alone, and the second group consisted of 10 newly diagnosed GBM patients at least four weeks post radiation therapy (with adjuvant temozolomide) that received TTField therapy combined with maintenance temozolomide. The treatment duration in individual patients varied between one and one and a half years, and all histological samples were independently examined in two laboratories in two countries. Twenty percent of the participants in the pilot study (4 out of 20) survived until the time of their report, roughly seven years. The individuals showed no clinical or radiological signs of recurrence and were no longer receiving any treatment. The authors suggest that in order to increase the probability of response to TTField therapy and subsequent long term survival, TTField treatment should be continued even in the face of initial radiologic tumor growth.

There is a lack of published evidence from randomized controlled trials examining the long-term safety and effectiveness of TTF as a treatment for tumors other than GBM, including non-small cell lung, brain metastasis, pancreatic cancer, ovarian cancer and mesothelioma. .

### **NovoTAL™ Simulation System**

There is limited published clinical evidence related to the NovoTAL™ simulation system and insufficient data to support improved long-term health outcomes with its use. This includes a small case series (Connelly et al., 2016), human head model (Wenger et al., 2015) and a user group survey (Chaudry et al., 2015). A framework for the use of NovoTAL in treatment planning has been proposed by Trusheim et al. (2016).

### **U.S. FOOD AND DRUG ADMINISTRATION (FDA)**

The Optune is categorized by the FDA as a stimulator, low electric field, tumor treatment; it is assigned product code NZK. Refer to the following website for additional information on supplemental FDA approvals for the Optune: <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfPMA/pma.cfm>. (Accessed September 15, 2017)

NovoTAL simulation software is not regulated by the FDA.

## CENTERS FOR MEDICARE AND MEDICAID SERVICES (CMS)

Medicare does not have a National Coverage Determination (NCD) for electric tumor treatment field therapy. Local Coverage Determinations (LCDs) do exist; see the LCDs for [Tumor Treatment Field Therapy \(TTFT\)](#). (Accessed July 31, 2017)

## COVERAGE RATIONALE

**The use of U.S. Food and Drug Administration (FDA) approved devices to generate electric tumor treatment fields (TTF) to treat newly diagnosed histologically-confirmed Supratentorial glioblastoma (known also as glioblastoma multiforme [GBM] or World Health Organization [WHO] grade IV astrocytoma) is proven and medically necessary when used according to FDA labeled indications, contraindications, warnings and precautions, and when ALL of the following criteria are met:**

- Initial treatment with radiation therapy has been completed; and
- Individual is receiving Temozolomide; and
- Individual has a Karnofsky Performance Status (KPS) score of  $\geq 60$ ; and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

### **Recurrent GBM**

**The use of FDA approved devices to generate electric TTF is proven and medically necessary following radiologically-confirmed recurrence of GBM in the supratentorial region of the brain after initial chemotherapy and when ALL of the following criteria are met:**

- The device is used as a monotherapy
- Individual has a KPS score of  $\geq 60$ ; and
- Individual or caregiver has been trained and is willing and able to apply the device daily; and
- Individual is willing to wear the device at least 18 hours daily.

When all of the above criteria are met for either newly diagnosed or recurrent GBM, an initial 3 months of electric TTF therapy will be approved.

Subsequent approval(s) for continuation of electric TTF is based on:

- MRI scan has been performed  $\leq 2$ -4 months prior to request and documents no evidence of disease progression. ; and
- KPS score of  $\geq 60$ ; and
- Documentation that the individual has been wearing the device at least 18 hours daily.

**The use of devices to generate electric tumor treatment fields (TTF) is considered investigational, unproven, and not medically necessary when the criteria above are not met and for all other indications.**

The FDA has not approved the use of electric TTF devices for indications other than GBM. Further studies are needed to determine the safety and long-term efficacy of electric TTF therapy for other types of cancer.

**Computer software used for therapeutic radiology clinical treatment planning in conjunction with electric tumor treatment field (TTF) therapy is unproven and not medically necessary.**

There is insufficient evidence to establish the efficacy of these products in the long-term outcomes of patients receiving electric TTF therapy.

## DEFINITIONS

**Karnofsky Performance Status (KPS):** A standard way of measuring the ability of cancer patients to perform ordinary tasks. KPS scores range from 0 to 100; a higher score means a person is better able to carry out daily activities. For example, a KPS of 60 means a person requires occasional assistance, but is able to care for most of their personal needs. KPS may be used to determine a patient's prognosis, to measure changes in a patient's ability to function, or to decide if a patient could be included in a clinical trial (National Cancer Institute [NCI], 2018).

**Supratentorial:** The upper portion of the brain comprised of the cerebrum and the diencephalon (NCI, 2018).

**Temozolomide:** An oral alkylating chemotherapy drug used in the treatment of some brain cancers. It is a first-line treatment for glioblastoma (NCI, 2018).

## APPLICABLE CODES

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies and Coverage Determination Guidelines may apply.

CPT Code	Description
77299	Unlisted procedure, therapeutic radiology clinical treatment planning <i>CPT® is a registered trademark of the American Medical Association</i>
HCPCS Code	Description
E0766	Electrical stimulation device used for cancer treatment, includes all accessories, any type

## DESCRIPTION OF SERVICES

Electric tumor treatment field (TTF) therapy (also known as tumor-treating fields, TTFields, ETTFs) is based on the principle that low intensity, intermediate frequency electric fields (100 to 300 kHz) have an anti-mitotic effect which acts during late metaphase and anaphase, with specific frequencies affecting specific cell types (Rulseh et al, 2012).

Alternating electrical fields within the human body that disrupt the rapid cell division exhibited by cancer cells, with the alternating electrical fields applied to the brain through transducer arrays placed on the scalp. TTF harness electric fields to arrest the proliferation of tumor cells and to destroy them. The TTF technology takes advantage of the special characteristics and geometrical shape of dividing cells, which make them susceptible to the effects of the alternating electric TTFields. These special fields alter the tumor cell polarity at an intermediate frequency (on the order of 100-300 kHz). The frequency used for a particular treatment is specific to the cell type being treated (e.g., 200kHz for GBM). In contrast, the TTFields have not been shown to have an effect on cells that are not undergoing division. Since most normal adult brain cells proliferate very slowly, if at all, they are hypothesized to be little affected by the TTFields (Novocure, 2018).

Glioblastoma multiforme (GBM) is the most prevalent and primary malignant brain tumor in adults, accounting for 54% of all gliomas. GBM is the most lethal brain tumor with only a third of patients surviving for one year and less than 5% living beyond 5 years. Unfortunately most glioblastomas recur (National Comprehensive Cancer Network [NCCN], 2018). It develops from star-shaped glial cells (astrocytes and oligodendrocytes) that support the health of the nerve cells within the brain.

The mainstay of treatment for GBM is surgery, followed by radiation and chemotherapy. The primary objective of surgery is to remove as much of the tumor as possible without injuring the surrounding healthy brain tissue needed for normal neurological function (such as motor skills, the ability to speak and walk, etc.). However, GBMs are surrounded by a zone of migrating, infiltrating tumor cells that invade surrounding tissues, making it impossible to ever remove the tumor entirely. Surgery provides the ability to reduce the amount of solid tumor tissue within the brain, remove those cells in the center of the tumor that may be resistant to radiation and/or chemotherapy and reduce intracranial pressure (American Association of Neurological Surgeons [AANS], 2018).

The Optune®, formerly the NovoTTF-100A System, (Novocure, Portsmouth NH) was approved by the FDA in April 2011, as a novel device to treat adults age 22 years or older with GBM that recurs or progresses after receiving chemotherapy and radiation therapy.

A supplemental FDA premarket approval was received in October 2015 for Optune™ with Temozolomide in adult patients with newly diagnosed, Supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy. For newly diagnosed GBM, Optune is not intended to be used as a substitute for standard treatments but rather as an adjunct therapy.

Refer to the [U.S. Food and Drug Administration \(FDA\)](#) section for additional information.

The Optune kit contains the portable electric field generator (Optune device), INE (insulated electrode) transducer arrays, power supply, and additional supplies. Prior to treatment, transducer arrays are placed on the patient's scalp according to the tumor's location, which are then covered by a lightweight white cap which resembles a bandage. The patient receives the noninvasive TTF treatment for at least 18 continuous hours per day for a minimum of 4 weeks. As the Optune device is portable, patients are able to carry out every-day activities.

Treatment parameters are preset by the manufacturer such that there are no electrical output adjustments available to the patient. The patient or caregiver must learn to change and recharge depleted device batteries and to connect to an external power supply overnight. In addition, the transducer arrays need to be replaced once to twice a week and the scalp re-shaved in order to maintain optimal contact.

The NovoTAL™ (transducer array layout) system is optional simulation software for use in clinical treatment planning with Optune therapy that may be leased from the manufacturer. Its purpose is to determine the optimal location of the transducer arrays based on the patient's most recent magnetic resonance imaging (MRI) scan, head size, and tumor location.

TTF technology is also being studied through ongoing clinical trials as a treatment for other solid tumors such as non-small cell lung cancer, brain metastasis, pancreatic cancer, ovarian cancer, and mesothelioma.

## CLINICAL EVIDENCE

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guideline for Central Nervous System Cancers, anaplastic gliomas/glioblastoma, includes standard brain radiation therapy (RT) + concurrent temozolomide and adjuvant temozolomide + alternating electric field therapy for patients with good performance status and either methylated or unmethylated/indeterminate MGMT promoter status, in whom resection was not feasible with the following footnote: "Alternating electric field therapy is only an option for patients with supratentorial disease" (category 1). For recurrence of GBM (GLIO-5), the guideline includes consideration of alternating electric treatment fields for glioblastoma after surgery, radiation and chemotherapy (category 2B) (NCCN, 2018).

Stupp et al. (2017) reported final outcomes from the randomized, open-label trial of 695 patients with glioblastoma whose tumor was resected or biopsied and had completed concomitant radiochemotherapy (median time from diagnosis to randomization, 3.8 months) and Optune therapy. Of the 695 randomized patients (median age, 56 years; IQR, 48-63; 473 men [68%]), 637 (92%) completed the trial. Median progression-free survival from randomization was 6.7 months in the TTFields-temozolomide group and 4.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.52-0.76;  $P < .001$ ). Median overall survival was 20.9 months in the TTFields-temozolomide group vs 16.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ). Systemic adverse event frequency was 48% in the TTFields-temozolomide group and 44% in the temozolomide-alone group. Mild to moderate skin toxicity underneath the transducer arrays occurred in 52% of patients who received TTFields-temozolomide vs no patients who received temozolomide alone. In the final analysis of this randomized clinical trial of patients with glioblastoma who had received standard radiochemotherapy, the addition of TTFields to maintenance temozolomide chemotherapy vs maintenance temozolomide alone, resulted in statistically significant improvement in progression-free survival and overall survival. These results are consistent with the previous interim analysis.

In a secondary analysis of the Stupp et al. (2017) trial, Taphoorn et al. (2018) examined the association of TTFields therapy with progression-free survival and HRQoL among patients with glioblastoma. Of the 695 patients in the study, 639 (91.9%) completed the baseline HRQoL questionnaire. Of these patients, 437 (68.4%) were men; mean (SD) age, 54.8 (11.5) years. Health-related quality of life did not differ significantly between treatment arms except for itchy skin. Deterioration-free survival was significantly longer with TTFields for global health (4.8 vs 3.3 months;  $P < .01$ ); physical (5.1 vs 3.7 months;  $P < .01$ ) and emotional functioning (5.3 vs 3.9 months;  $P < .01$ ); pain (5.6 vs 3.6 months;  $P < .01$ ); and leg weakness (5.6 vs 3.9 months;  $P < .01$ ), likely related to improved progression-free survival. Time to deterioration, reflecting the influence of treatment, did not differ significantly except for itchy skin (TTFields worse; 8.2 vs 14.4 months;  $P < .001$ ) and pain (TTFields improved; 13.4 vs 12.1 months;  $P < .01$ ). Role, social, and physical

functioning were not affected by TTFields. The addition of TTFields to standard treatment with temozolomide for patients with glioblastoma results in improved survival without a negative influence on HRQoL except for more itchy skin, an expected consequence from the transducer arrays.

In a multinational, open-label, randomized phase III trial (EF-14 trial), Stupp et al. (2015) compared Optune in combination with temozolomide to temozolomide alone in 700 patients age 18 and over with newly diagnosed GBM. The interim report revealed that in the intent-to-treat population, patients treated with TTFields plus temozolomide showed a statistically significant increase in progression free survival (PFS), the primary endpoint, compared to temozolomide alone (median PFS 7.1 months versus 4.0 months, hazard ratio=0.62, p=0.0013). In the per-protocol population, patients treated with TTFields plus temozolomide demonstrated a statistically significant increase in OS, a powered secondary endpoint, compared to temozolomide alone (median OS 20.5 months versus 15.6 months, hazard ratio=0.64, p=0.0042). In the intent-to-treat population, the median OS was 19.6 months versus 16.6 months, respectively, hazard ratio=0.74 (p=0.0329). The two-year survival rate was 50 percent greater with TTFields plus temozolomide versus temozolomide alone: 43 percent versus 29 percent. The trial's independent data monitoring committee concluded that the study met its endpoints at its pre-specified interim analysis of the first 315 patients with 18 months or more of follow-up. The committee recommended that the trial be terminated early for success and that all control patients be offered TTFields therapy even prior to progression. In addition, the authors reported that the trial showed Optune could be safely combined with temozolomide. There was no significant increase in systemic toxicities from Optune reported in combination with temozolomide versus temozolomide alone. The most common adverse reaction from Optune treatment was mild to moderate skin irritation, which according to the authors was easily managed, reversible and did not result in treatment discontinuation. This clinical trial has some important limitations. Patient enrollment occurred only after the end of radiochemotherapy, leading to some variation in the delivery of standard treatment of temozolomide and radiotherapy. Patients who had progressed early during radiochemotherapy were not eligible for randomization, thus excluding patients with very poor prognoses. There is likely reporting bias for second-line therapies after tumor progression because in the TTFields plus temozolomide group, TTFields were to be continued, and thus, more detailed treatment information has been tracked for this group.

Stupp et al. (2012) completed a phase III randomized trial (EF-11 trial) of chemotherapy-free treatment of Novo tumor treatment fields (TTF) (20-24h/day) versus active chemotherapy in the treatment of patients with recurrent glioblastoma. The primary end-point was improvement of overall survival. Patients (median age 54 years (range 23-80), Karnofsky performance status 80% (range 50-100) were randomized to TTF alone (n=120) or active chemotherapy control (n=117). Number of prior treatments was two (range 1-6). Median survival was 6.6 versus 6.0 months (hazard ratio 0.86 [95% CI 0.66-1.12]; p=0.27), 1-year survival rate was 20% and 20%, progression-free survival rate at 6 months was 21.4% and 15.1% (p=0.13), respectively in TTF and active control patients. Responses were more common in the TTF arm (14% versus 9.6%, p=0.19). The TTF-related adverse events were mild (14%) to moderate (2%) skin rash beneath the transducer arrays. Severe adverse events occurred in 6% and 16% (p=0.022) of patients treated with TTF and chemotherapy, respectively. Quality of life analyses favored TTF therapy in most domains. Although no improvement in overall survival was demonstrated, the authors conclude that the efficacy and activity with this chemotherapy-free treatment device appears comparable to chemotherapy regimens that are commonly used for recurrent glioblastoma and that toxicity and quality of life favored TTF.

A treatment-based analysis of data from the pivotal phase III trial of the NovoTTF-100A System™ versus best physician's choice (BPC) chemotherapy was conducted by Kanner et al. (2014) in patients with recurrent glioblastoma multiforme (GBM), with particular focus on efficacy in patients using NovoTTF therapy as intended. Median overall survival (OS) was compared for recurrent GBM patients receiving at least one full cycle of treatment with NovoTTF-100A System or BPC chemotherapy (modified intention-to-treat [mITT] population). The relationship between NovoTTF-100A System compliance and OS was evaluated in the ITT population. Kaplan-Meier analyses examined treatment-related differences in OS for various patient subgroups. Median OS was significantly higher in patients receiving ≥1 course of NovoTTF therapy versus BPC (7.7 v 5.9 months; hazard ratio, 0.69; 95% confidence interval [CI], 0.52-0.91; P = .0093). Median OS was also significantly higher in patients receiving NovoTTF therapy with a maximal monthly compliance rate ≥75% (≥18 hours daily) versus those with a <75% compliance rate (7.7 v 4.5 months; P = .042), and Kaplan-Meier analysis demonstrated a significant trend for improved median OS with higher compliance (P = .039). Additional post hoc analysis showed significantly higher median OS with NovoTTF therapy than with BPC for patients with prior low-grade glioma, tumor size ≥18 cm(2), Karnofsky performance status ≥80, and those who had previously failed bevacizumab therapy. This contrasts with the equivalent efficacy reported previously based on analysis of all randomized ITT subjects, including many who did not receive a full cycle of treatment. The authors summarized that results from the present study suggest that when used as intended, NovoTTF Therapy provides efficacy superior to that of chemotherapy in a heterogeneous population of patients with recurrent GBM. Post hoc analyses identified subgroups of patients who may be particularly good candidates for NovoTTF Therapy, pending further confirmatory studies.

Wong et al, (2015) conducted a retrospective chart review from a single institution on patients treated with NovoTTF-100A and bevacizumab between November 2011 and December 2013. The patients were segregated into two cohorts:

(i) those treated with NovoTTF-100A and bevacizumab only and (ii) those treated with NovoTTF-100A, bevacizumab and TCCC. Response to treatment was measured according to the Response Assessment in Neuro-Oncology criteria. Progression-free survival (PFS) and OS were measured from the time of application of these treatments to death or last follow up. The cohort treated with NovoTTF-100A, bevacizumab, and TCCC ( $n = 3$ ) did not differ significantly from the rest of the cohort treated with NovoTTF-100A and bevacizumab only ( $n = 34$ ). Potential reasons for this include baseline clinical characteristics and dexamethasone use. The authors note limitations with this review to be the number of patients treated with NovoTTF-100A, bevacizumab, and TCCC is small and therefore they cannot recommend this combination as standard clinical practice. However, they commented that the findings in their patients are notable and it can serve as a basis for future clinical trials. Second, it is unclear what the relative contribution of immunosuppression in the periphery versus the tumor microenvironment has on treatment resistance in recurrent glioblastomas. Therefore, they conclude that combination treatment, rather than single-agent monotherapy, will more likely affect meaningful clinical results.

Wong et al. (2014) analyzed the characteristics of responders and nonresponders in both cohorts of the phase III trial which compared NovoTTF-100A Best Physician's Choice (BPC) chemotherapy for recurrent glioblastoma to determine the characteristics of response and potential predictive factors. Their analysis showed that a significantly higher proportion of NovoTTF-100A responders, five of 14 (36%), had prior low-grade histologies while none of seven (0%) BPC responder had this type of histological characteristics, suggesting that secondary glioblastoma may be more responsive to NovoTTF-100A treatment. Because primary and secondary glioblastomas have different genetic alterations, notably *EGFR* and *MDM2* amplifications together with *p16* deletion in primary glioblastomas and mutation, *IDH1* mutation and *PDGFR* amplification in secondary glioblastomas, the distinct genetic makeup in these two subtypes of glioblastomas could make secondary glioblastomas more susceptible to NovoTTF-100A treatment. Secondary glioblastomas and low dexamethasone usage are associated with a higher proportion of NovoTTF-100A responders but not BPC chemotherapy responders. The authors surmise that during treatment with NovoTTF-100A, this slower rate of tumor progression might allow enough time for the efficacy of TTFs to emerge because it may take multiple mitotic cycles to reduce the number of tumor cells and the size of the glioblastoma. The authors recommend that future clinical trials on the NovoTTF-100A device must include stratification of potential predictive factors of response that include both genetic and epigenetic determinants.

Mrugala et al. (2014) evaluated data collected from all adult patients with recurrent GBM who began commercial Novocure TTF therapy through the Patient Registry Dataset (PRiDe), which is a post-marketing registry of all recurrent GBM patients who received NovoTTF therapy in a real-world, clinical practice setting in the United States between 2011 and 2013. Data from 457 recurrent GBM patients who received Novocure TTF therapy in 91 US cancer centers were analyzed. More patients in PRiDe than the EF-11 trial received Novocure TTF therapy for first recurrence (33% v 9%) and had received prior bevacizumab therapy (55.1% v 19%). Median OS was significantly longer with Novocure TTF therapy in clinical practice (PRiDe data set) than in the EF-11 trial (9.6 v 6.6 months; HR, 0.66; 95% CI, 0.05 to 0.86,  $P = .0003$ ). One- and 2-year OS rates were more than double for Novocure TTF therapy patients in PRiDe than in the EF-11 trial (1-year: 44% v 20%; 2-year: 30% v 9%). First and second versus third and subsequent recurrences, high Karnofsky performance status (KPS), and no prior bevacizumab use were favorable prognostic factors. No unexpected adverse events were detected in PRiDe. As in the EF-11 trial, the most frequent adverse events were mild to moderate skin reactions associated with application of the Novocure TTF therapy transducer arrays. The authors concluded that results from PRiDe, together with those previously reported in the EF-11 trial, indicate that Novocure TTF therapy offers clinical benefit to patients with recurrent GBM, has high patient tolerability and favorable safety profile in the real-world, clinical practice setting.

Rulseh et al. (2012) reported the long-term survival of patients with glioblastoma multiforme treated with tumor-treating fields in a small pilot study of 20 individuals. The inclusion criteria of the study included a KPS  $\geq 70\%$  and age  $\geq 18$  years, and the patients were divided into two groups. The first group consisted of 10 patients diagnosed with recurring GBM after failing temozolomide treatment that were treated with TTF therapy alone, and the second group consisted of 10 newly diagnosed GBM patients at least four weeks post radiation therapy (with adjuvant temozolomide) that received TTF therapy combined with maintenance temozolomide. The treatment duration in individual patients varied between one and one and a half years, and all histological samples were independently examined in two laboratories in two countries. Twenty percent of the participants in the pilot study (4 out of 20) survived until the time of their report, roughly seven years. The individuals showed no clinical or radiological signs of recurrence and were no longer receiving any treatment. The authors suggest that in order to increase the probability of response to TTF therapy and subsequent long term survival, TTF treatment should be continued even in the face of initial radiologic tumor growth.

There is a lack of published evidence from randomized controlled trials examining the long-term safety and effectiveness of TTF as a treatment for tumors other than GBM, including non-small cell lung, brain metastasis, pancreatic cancer, ovarian cancer and mesothelioma.

## **NovoTAL™ Simulation System**

There is limited published clinical evidence related to the NovoTAL™ simulation system, and insufficient data to support improved long-term health outcomes with its use. This includes a small case series (Connelly et al., 2016), human head model (Wenger et al., 2015), and a user group survey (Chaudry et al., 2015). A framework for the use of NovoTAL in treatment planning has been proposed by Trusheim et al. (2016).

## **U.S. FOOD AND DRUG ADMINISTRATION (FDA)**

The Optune is categorized by the FDA as a stimulator, low electric field, tumor treatment; see the following website for the initial Premarket Approval information:

<https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm?id=P100034S013>. (Accessed July 5, 2018)

Refer to the following website for additional information on supplemental FDA approvals for the Optune using product code NZK: <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpMA/pma.cfm>. (Accessed July 16, 2018)

NovoTAL simulation software is not regulated by the FDA.

## **CENTERS FOR MEDICARE AND MEDICAID SERVICES (CMS)**

Medicare does not have a National Coverage Determination (NCD) for electric tumor treatment field therapy. Local Coverage Determinations (LCDs) exist, see the LCDs for [Tumor Treatment Field Therapy \(TTFT\)](#). (Accessed June 12, 2018)

## POLICY STATEMENT:

- I. Based upon our criteria and assessment of peer-reviewed literature, alternating electrical field therapy (Tumor-Treatment Field (TTF) therapy) using Optune® (Novocure Inc, Portsmouth, New Hampshire) for treatment of recurrent Glioblastoma multiforme (GBM) is considered **medically appropriate** when all of the following criteria have been met:
  - A. 1<sup>st</sup> or 2<sup>nd</sup> recurrence of GBM; and
  - B. The individual has a Karnofsky Performance Status (KPS) of 90 or greater; and
  - C. The individual has not received prior treatment with Bevacizumab; and
  - D. The device is to be used as monotherapy after failure of standard medical therapy (e.g., chemotherapy, surgery, and radiation therapy).
  - E. There is documented evidence the member is compliant with the TTF device during a one month trial period. Compliance is defined as use of the device for 18 hours or more per day during the one month trial period.
- II. Based upon our criteria and assessment of peer-reviewed literature, alternating electrical field therapy (Tumor-Treatment Field (TTF) therapy) using Optune® (Novocure Inc, Portsmouth, New Hampshire) for treatment of newly diagnosed Glioblastoma multiforme (GBM) is considered **medically appropriate** when the following criteria have been met:
  - A. The device is to be used as an adjunct with the chemotherapy drug temozolomide (TMZ); and
  - B. Following standard treatments that include maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy.

## POLICY GUIDELINES:

- I. The Optune® (Novocure Inc, Portsmouth, New Hampshire) will be allowable for up to 6 months if the patient is compliant with the regimen. Continued use after 6 months will require additional documentation to show no progression in the patient's condition.
- II. The Optune® (Novocure Inc, Portsmouth, New Hampshire) is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM).
- III. The Optune® (Novocure Inc, Portsmouth, New Hampshire) was approved by the U.S. Food and Drug Administration (FDA) in April 2011 to deliver TTF therapy and is intended as a treatment for adult patients (22 years of age or older) with confirmed glioblastoma multiforme, following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment, and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted.
- IV. The Optune® (Novocure Inc, Portsmouth, New Hampshire) was approved by the U.S. Food and Drug Administration (FDA) in October 2015 to deliver TTF therapy and is intended as a treatment for adult patients (22 years of age or older) with newly-diagnosed glioblastoma multiforme when given along with the chemotherapy drug temozolomide following standard treatments that include surgery, and radiation therapy and chemotherapy used together.
- V. The Federal Employee Health Benefit Program (FEHBP/FEP) requires that procedures, devices or laboratory tests approved by the U.S. Food and Drug Administration (FDA) may not be considered investigational and thus these procedures, devices or laboratory tests may be assessed only on the basis of their medical necessity.

<b>SUBJECT: TUMOR–TREATMENT FIELD THERAPY FOR GLIOBLASTOMA</b>  <b>POLICY NUMBER: 6.01.45</b> <b>CATEGORY: Technology Assessment</b>	<b>EFFECTIVE DATE: 05/28/15</b> <b>REVISED DATE: 08/18/16, 08/17/17, 04/19/18</b>  <b>PAGE: 2 OF: 5</b>
---	--

## **DESCRIPTION:**

Glioblastoma multiforme (GBM) is the most common and aggressive primary intracranial tumor with approximately 33% surviving 1 year and less than 5% surviving more than 5 years. Median survival with optimal therapy has been reported to be 10-15 months with most tumors recurring within 7-9 months despite multimodal treatment (e.g. repeat surgery, re-irradiation and chemotherapy). Choice of chemotherapy for treatment in the case of recurrence varies but may include alkylating agents (e.g., lomustine, carmustine, procarbazine), re-treatment with temozolomide, and more recently, bevacizumab either alone or in combination with other agents. Overall survival after recurrence is relatively short even with optimal therapy. New or novel treatments such as TTF therapy are being investigated to improve survival in patients with GBM.

TTF therapy is delivered via the Optune® (Novocure Inc, Portsmouth, New Hampshire) which is a battery-powered, portable device that generates alternating low intensity, intermediate electrical fields (100-300 kHz) by four disposable electrode arrays (replaced 1-2 times per week) that are noninvasively attached to the patient's shaved scalp placed in such a way to encompass the tumor. The alternating low intensity electrical field is thought to disrupt cell division of the cancer cells so that either cell division does not occur or it is ineffective, resulting in death of the cancer cells without harming the normal healthy cells. The device is used by the patient at home on a continuous basis (20-24 h/d) for the duration of treatment, which can last for several months. Patients can carry the device in a backpack or shoulder pack while carrying out activities of daily living.

## **RATIONALE:**

The Food and Drug Administration approval of the Optune® device formally NovoTTF-100A system was based on a phase 3, multinational prospective RCT (Stupp et al, 2012). Two hundred thirty-seven patients with relapsed or progressive glioblastoma multiforme (GBM), despite conventional radiotherapy were randomized in a 1:1 ratio to receive TTF therapy (delivered by the NovoTTF-100A System) only (n=120) or the best standard of care chemotherapy (active control) (n=117). The choice of chemotherapy regimens varied, reflecting local practice at each of the 28 participating clinical centers which were across 7 countries. Patient characteristics were balanced in both groups, with median age of 54 years and median Karnofsky Performance Status (KPS) score of 80%. More than 80% of participants had failed 2 or more prior chemotherapy regimens, and 20% had failed bevacizumab prior to study enrollment. Ninety-seven percent (116) of 120 participants in the TTF group started treatment and 93 participants (78%) completed 1 cycle (4 weeks) of therapy. Discontinuation of TTF therapy occurred in 27 participants (22%) due to noncompliance or the inability to handle the device. For each TTF treatment month, the median compliance was 86% (range, 41%-98%), which equaled a mean use of 20.6 hours per day. In the active control group, 113 (97%) of the 117 assigned participants received chemotherapy and all except 1 individual completed a full treatment course. Twenty-one participants (18%) in the active control group did not return to the treating site and details on disease progression and toxicity were not available. This RCT did not reach its primary end point of improved survival compared with active chemotherapy. With a median follow-up of 39 months, 220 participants (93%) had died. Median survival was 6.6 months in the TTF group compared with 6.0 months in the active control group (hazard ratio, 0.86; 95% confidence interval [CI], 0.66 to 1.12; p=0.27). For both groups, 1-year survival was 20%. The survival rates for 2- and 3-year survival were 8% and 4%, respectively, for the TTF group versus 5% and 1%, respectively, for the active control group. PFS rate at 6 months was 21.4% in the TTF group, compared with 15.1% in the active control group (p=0.13). Objective radiologic responses (partial and complete response) were noted in 14 participants in the TTF group and 7 in the active control group, with a calculated response rate of 14.0% (95% CI, 7.9% to 22.4%) versus 9.6% (95% CI, 3.9% to 18.8%), respectively. Sixteen percent of the TTF participants had grade 1 and 2 contact dermatitis on the scalp, which resolved with topical corticosteroids. Active control participants experienced grade 2-4 events by organ system related to the pharmacologic activity of chemotherapy agents used; severe (grades 3 and 4) toxicity was observed in 3% of participants. Longitudinal quality of life (QOL) data were available in 63 participants (27%). There were no meaningful differences observed between the groups in the domains of global health and social functioning. However, cognitive, emotional, and role functioning favored TTF therapy, whereas physical functioning favored chemotherapy. Symptom scale analysis was in accordance to treatment-associated toxicity; appetite loss, diarrhea, constipation, nausea, and vomiting were directly related to the chemotherapy administration. Increased pain and fatigue was reported in the chemotherapy-treated patients and not in the TTF group. In summary, this RCT failed to demonstrate the primary end point of improved survival with

<b>SUBJECT: TUMOR–TREATMENT FIELD THERAPY FOR GLIOBLASTOMA</b>  <b>POLICY NUMBER: 6.01.45</b> <b>CATEGORY: Technology Assessment</b>	<b>EFFECTIVE DATE: 05/28/15</b> <b>REVISED DATE: 08/18/16, 08/17/17, 04/19/18</b>  <b>PAGE: 3 OF: 5</b>
---	--

TTF therapy in comparison to chemotherapy. Limitations of the trial included a somewhat heterogeneous patient population, with participants included after progression of 1 or several lines of chemotherapy, as well as the use of different chemotherapy regimens in the control group. Another limitation is the absence of a placebo/supportive care arm. In the setting of advanced disease, the supportive care arm would have been useful to gauge the safety and efficacy of treatment for both groups of patients. Treatments used in the active control arm (best standard of care chemotherapy) in the recurrent disease setting have previously demonstrated limited efficacy, thus limiting the ability to determine the true treatment effect of TTF. Data from a trial of TTF versus placebo, or TTF plus standard chemotherapy versus standard chemotherapy alone would therefore provide a better assessment of treatment efficacy.

A subgroup analysis of patient data of this phase 3 trial (Wong et al, 2014) evaluated the different characteristics of responders and nonresponders in the TTF group compared to the active control group. More patients in the TTF arm were considered responders (14/120 vs 7/117 in the chemotherapy arm.) Median response time was longer for those in the TTF arm than the chemotherapy arm (7.3 months vs 5.6 months,  $p<0.001$ ), and there was a strong correlation (Pearson's  $r$ ) between response and OS in the TTF arm ( $p<0.001$ ) but not in chemotherapy arm ( $p=0.29$ ). Compared with the chemotherapy arm, a higher proportion of responders in the TTF arm had a prior low-grade histology (36% vs 0%). These differences in treatment responder groups suggest that TTF therapy may differentially benefit certain types of GBM; however, the small numbers of responders in both groups limits generalizations that can be drawn from this analysis.

Analysis of the NovoTTF-100A™ Patient Registry Dataset (PRiDe) of 457 patients with recurrent GBM who were treated with NovoTTF therapy in the United States between October 2011 and November 2013 and comparison to patient data in the Phase 3 trial was performed (Mrugula et al 2014) to provide a larger dataset of patients with recurrent GBM treated with TTF therapy. No new adverse events in the PRiDe group of patients were reported compared to the Phase 3 trial group. However median overall survival was longer in the TTF group in the PriDe group (9.6 months) compared to the TTF group in the Phase 3 trial (6.6 months) or in the active chemotherapy group (6.0 months). Median treatment time was almost double for the TTF PriDe group compared to either the TTF or chemotherapy group in the Phase 3 trial. Favorable prognostic factors in the PriDe group included 75% or more daily compliance of the device, treatment with TTF at first recurrence, no prior treatment with bevacizumab, and Karnofsky Performance Score (KPS) 90 or greater. The authors suggest there are subsets of patients who derive significant benefit from TTF therapy and that TTF therapy using the NovoTTF-100A™ device is safe and efficacious to treat recurrent GBM.

The Food and Drug Administration approval of the Optune® device formally NovoTTF-100A system for newly diagnosed glioblastoma multiforme (GBM) was based on the results from a clinical trial involving 695 patients newly diagnosed with GBM that compared those who used the device with temozolomide (TMZ) to those receiving TMZ alone (Stupp, 2015). Patients who used the device along with TMZ lived, on average, about 7 months with no disease progression compared to 4 months for those who had the drug alone. The device plus TMZ group survived for an average of 19.4 months after starting treatment compared to 16.6 months for those who were treated with TMZ alone.

The use of TTF therapy has been described in a number of case series. However, without evidence from additional high quality comparative studies, these studies provide limited additional evidence about whether TTF therapy improves outcomes compared with currently available therapy for GBM.

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines for Central Nervous System (v 1.2016) states that alternating electrical field therapy for glioblastoma may be considered as a treatment option for recurrent disease (Category 2A).

Medical Policy: 06.01.34

Original Effective Date: November 2014

Reviewed: October 2018

Revised: October 2018

## **BENEFIT APPLICATION:**

Benefit determinations are based on the applicable contract language in effect at the time the services were rendered. Exclusions, limitations or exceptions may apply. Benefits may vary based on contract, and individual member benefits must be verified. Wellmark determines medical necessity only if the benefit exists and no contract exclusions are applicable. This medical policy may not apply to FEP. Benefits are determined by the Federal Employee Program.

This Medical Policy document describes the status of medical technology at the time the document was developed. Since that time, new technology may have emerged or new medical literature may have been published. This Medical Policy will be reviewed regularly and be updated as scientific and medical literature becomes available.

## **DESCRIPTION:**

Glioblastoma is the most aggressive cancer that begins within the brain. Due to its multiple forms, it is also termed Glioblastoma multiforme (GBM). According to its location in the brain it may also give rise to hemiparesis, seizures, memory or speech impairment and visual changes. It is found to be more common in males than females. Currently there is no known cure but treatments are available. Tumor treatment fields (TTF) (e.g. Optune® device) is one such treatment that aims to prolong progression-free survival (PFS) and overall survival (OS).

Optune® (formerly NovoTTF-100A System) is the only legally marketed TTF delivery system available in the United States. The system used for the therapy consists of the Optune® Treatment Kit (Novocure, Ltd.) and INE Transducer Arrays. The kit includes the Electric Field Generator (NovoTTF-100A/Optune® device), power supply, portable battery, battery rack, battery charger, connection cable, and carrying case. The arrays are packaged with a gel layer, padding, medical tape, and overlapping liner. The portable, battery-powered device is carried in a backpack or shoulder pack while carrying out activities of daily living. For the treatment of glioblastoma, 4 disposable transducer arrays with insulated electrodes are applied to the patient's shaved head. The transducer array layout is typically determined using specialized software. The patient's scalp is re-shaved and the transducer arrays replaced twice a week by the patient, caregiver, or device technician. The device is worn for up to 24 hours a day for the duration of treatment, except for brief periods for personal hygiene and 2 to 3 days at the end of each month. The minimum daily treatment is 18 hours. The minimum duration of treatment is 1 month, with the continuation of treatment available until recurrence.

In April 2011, the NovoTTF-100A™ System (Novocure; assigned the generic name of TTF) was approved by the U.S. Food and Drug Administration (FDA) through the premarket approval process. The FDA-approved label reads as follows: "The NovoTTF-100A System is intended as a treatment for adult patients (22 years of age or older) with confirmed glioblastoma multiforme (GBM), following confirmed recurrence in an upper region of the brain (supratentorial) after receiving chemotherapy. The device is intended to be used as a stand-alone treatment and is intended as an alternative to standard medical therapy for recurrent GBM after surgical and radiation options have been exhausted."

In September 2014, FDA approved Novocure's request for a product name change from NovoTTF-110A System to Optune®.

In October 2015, FDA expanded the indication for Optune® in combination with temozolomide to include newly diagnosed GBM. The device was granted priority review status in May 2015 because there was no legally marketed alternative device available for the treatment of newly diagnosed GBM, a life-threatening condition. In July 2016, a smaller, lighter version of the Optune® device, called the Optune® System (NovoTTF-200A System), received FDA approval.

The FDA-approved label for newly diagnosed GBM reads as follows: "This device is indicated as treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM). Optune® with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery and completion of radiation therapy together with concomitant standard of care chemotherapy."

The mechanism of action as described by the manufacturer: Tumor treating fields (TTF)/Electric tumor treatment fields is a locally or regionally delivered treatment that produces electric fields within the human body to disrupt the rapid cell division exhibited by cancer cells. TTF therapy works by creating alternating, "wave-like" electric fields that travel across their region of usage in different directions. Because structures within dividing cells have an electric charge, they interact with these electric fields.

## **MAPPING SOFTWARE TO OPTIMIZE TTF THERAPY (E.G. NOVOTAL™ SIMULATION SYSTEM)**

The NovoTAL™ (Transducer Array Layout) System (Novocure Inc.) is a proprietary software tool that produces a custom transducer array layout to optimize Optune therapy for each patient. According to the manufacturer of Optune® (TTF) that also developed the NovoTAL™ Simulation System: To ensure patients receive the maximal therapeutic level of TTFields at the site of their tumor, tumor burden is mapped and an optimal array layout is personalized using the NovoTAL software. The NovoTAL software utilizes magnetic resonance imaging (MRI) measurements for head size and tumor location obtained from axial and coronal T1 post contrast sequences to determine the optimal paired transducer array configuration that will deliver the maximal field intensity at the site of the tumor.

## **NEWLY DIAGNOSED GBM**

The primary treatment for glioblastoma multiforme (GBM) is debulking surgery to remove as much of the tumor as possible. At that time, some patients may undergo implantation of the tumor cavity with a carmustine (bis chloroethylnitrosourea [BCNU]) - impregnated wafer. Depending on the patient's physical condition, adjuvant radiation therapy, chemotherapy (typically temozolomide), or a combination of the 2 are given. After adjuvant therapy, some patients may undergo maintenance therapy with temozolomide.

In the adjuvant setting, Optune® demonstrated an improvement in overall survival (OS) when combined with temozolomide, when compared with the chemotherapy agent alone. In an analysis of 695 patients enrolled in the phase III EF-14 study, the median OS was 19.4 months with Optune® compared with 16.6 months with temozolomide alone. Additionally, progression-free survival (PFS) was improved by approximately 3 months, according to the FDA.

## **RECURRENT GBM**

Treatment of GBM is rarely curative, and tumors will recur in mostly all patients.

No standard treatment exists for recurrent GBM. In patients with disease that recurs after initial treatment, additional debulking surgery may be used if recurrence is localized. Other treatment options for recurrent disease include various forms of systemic medications such as bevacizumab, bevacizumab plus chemotherapy (e.g., irinotecan, bis-chloroethylnitrosourea/chloroethylnitrosourea, temozolomide), temozolomide, nitrosourea, procarbazine plus chloroethylnitrosourea and vincristine), cyclophosphamide, and platinum-based agents.

Clinical studies are ongoing to determine the safety and efficacy of TTF therapy as part of combination therapy for treating recurrent GBM. TTF therapy is under investigation as a combination therapy with chemotherapy plus bevacizumab and as a combination therapy with chemotherapy after irradiation therapy for treating recurrent GBM.

## **TREATMENT OUTSIDE OF GLIOBLASTOMA**

Tumor treating fields technology (TTF) is also being studied as a treatment for other solid tumors (e.g., melanoma, pancreatic adenocarcinoma and non-small cell lung cancer). However, there is a lack of published evidence from randomized controlled trials examining the long-term safety and effectiveness of TTF as a treatment of these cancers at this time.

## **GUIDELINES AND POSITION STATEMENTS**

## **THE NATIONAL COMPREHENSIVE CANCER NETWORK (NCCN)**

The National Comprehensive Cancer Network (NCCN) clinical practice guidelines on Central Nervous Systems Tumors (v.1.2018) recommend TTF therapy in conjunction with standard brain radiation therapy and current/adjuvant temozolomide for patients with supratentorial disease with good performance status. The panel conceded that data regarding TTF therapy is limited to evidence from the RCT which demonstrated similar survival in between groups. In addition, in the background section, the panel indicated that TTF therapy may be considered as a treatment option for recurrent GBM but not all panelists recommend treatment for these patients due to a lack of efficacy. The NCCN guideline does not advocate for the use of TTF therapy in the recommendation section for patients with recurrent disease.

## **KARNOFSKY PERFORMANCE STATUS SCORE**

A 10 point scale used by healthcare providers to quickly evaluate how an individual is feeling. This scale is used within the clinical guidelines algorithm.

- 100 Able to work. Normal; No complaints; No evidence of disease.
- 90 Able to work. Able to carry on normal activity; Minor symptoms.
- 80 Able to work. Normal activity with effort; some symptoms.
- 70 Independent; not able to work. Cares for self; Unable to carry on normal activity.
- 60 Disabled; dependent. Requires occasional assistance; cares for most needs.
- 50 Moderately disabled; dependent. Requires considerable assistance and frequent care.
- 40 Severely disabled; dependent. Requires special care and assistance.
- 30 Severely disabled. Hospitalized, death not imminent.
- 20 Very sick. Active supportive treatment needed.
- 10 Moribund. Fatal processes are rapidly progressing

## **EUROPEAN ASSOCIATION OF NEURO-ONCOLOGY (EANO)**

EANO Guideline on the Diagnosis and Treatment of Anaplastic Gliomas and Glioblastoma. 2014. This guideline states: "new approaches of glioma therapy... device based therapies such as tumor-treating fields should only be administered in the context of clinical trials."

## **EUROPEAN SOCIETY OF MEDICAL ONCOLOGY (ESMO)**

High-grade Glioma: ESMO Clinical Practice Guidelines for Diagnosis, Treatment and Follow-up. 2014. This guideline states: "Applying alternating electric fields—tumor-treating fields—using a battery powered device connected to electrodes placed on the patient's scalp—was compared with physicians' choice of chemotherapy in a randomized trial in recurrent disease. TTF failed to prolong survival compared with second-line chemotherapy [I, A]." This guideline defines Level of Evidence I as "evidence from at least one large randomized, controlled trial of good methodological quality (low potential for bias) or meta-analyses of well-conducted randomized trials without heterogeneity." This guideline defines Grade of Recommendation A as "strong evidence for efficacy with a substantial clinical benefit, strongly recommended."

Some clinical researchers assert that TTF "could be further evaluated in combination with chemotherapy, as a maintenance treatment, or as a salvage therapy if radiotherapy or surgery is not possible." Clinical studies are ongoing to determine the safety and efficacy of TTF therapy as part of combination therapy for treating recurrent GBM. TTF therapy is under investigation as a combination therapy with chemotherapy plus bevacizumab and as a combination therapy with chemotherapy after irradiation therapy for treating recurrent GBM.

## **NATIONAL INSTITUTE FOR HEALTH AND CARE EXCELLENCE (NICE)**

Guideline Brain Tumours (primary) and Brain Metastases in Adults (2018) This guideline manages suspected and confirmed glioma, suspected and confirmed meningioma, and suspected and confirmed brain metastases. It does not mention the use of tumor treatment fields.

## NATIONAL CANCER INSTITUTE (NIH)

### ADULT CENTRAL NERVOUS SYSTEM TUMORS TREATMENT (PDQ®)—HEALTH PROFESSIONAL VERSION-GLIOBLASTOMA TREATMENT

For patients with glioblastoma (WHO grade IV), the cure rate is very low with standard local treatment.

Standard treatment options for patients with newly diagnosed glioblastoma include the following:

1. Surgery plus radiation therapy and chemotherapy.
2. Surgery plus radiation therapy.
3. Carmustine-impregnated polymer implanted during initial surgery.
4. Radiation therapy and concurrent chemotherapy.

The standard treatment for patients with newly diagnosed glioblastoma is surgery followed by concurrent radiation therapy and daily temozolomide, and then followed by six cycles of temozolomide. The addition of bevacizumab to radiation therapy and temozolomide did not improve overall survival (OS).

The use of TTF is not mentioned within the information provided in the treatment section for Glioblastoma.

## DEFINITIONS

**Supratentorial** - the supratentorial region of the brain is the area located above the tentorium cerebelli. The area of the brain below the tentorium cerebelli is the infratentorial region. The supratentorial region contains the cerebrum, while the infratentorial region contains the cerebellum.

## PRIOR APPROVAL:

Not applicable.

## POLICY:

Tumor treating fields (TTF) therapy (e.g. Optune®) to treat glioblastoma multiforme is considered **medically necessary** as an adjunct to standard maintenance therapy with temozolomide in patients with **newly** diagnosed glioblastoma multiforme following initial treatment with surgery, radiotherapy, and chemotherapy when ALL of the following conditions are met:

- Adult patients ≥22 years of age **AND**
- Histologically-confirmed glioblastoma multiforme supratentorial tumor **AND**
- Karnofsky Performance Status score ≥60% **AND**
- Patient understands device use, including the requirement for a shaved head, and is willing to comply with use criteria according to the Food and Drug Administration label (at least 18 hours of use per day) **AND**
- Lack of implanted medical devices, including but not limited to: spinal cord stimulators, pacemakers, defibrillators, and programmable shunts.

Tumor treatment fields (TTF) therapy to treat glioblastoma is considered **investigational**, including but not limited to the following:

- As an adjunct to standard medical therapy (eg, bevacizumab, chemotherapy) for patients with **progressive or recurrent** glioblastoma multiforme OR
- As an alternative to standard medical therapy for patients with **progressive or recurrent** glioblastoma multiforme OR
- For brain metastases OR
- For cancer in other areas of the brain.

The use of tumor treatment fields (TTF) therapy to treat all other types of cancer is considered **investigational**.

For individuals who have progressive or recurrent GBM who receive TTF therapy as an adjunct or alternative to standard medical therapy, the evidence includes an RCT and nonrandomized comparative studies. Relevant outcomes are overall survival, disease-specific survival, quality of life, and treatment-related morbidity. The single RCT evaluating TTF therapy for recurrent GBM did not show superiority of TTF therapy for the primary outcome (overall survival) compared with physicians' choice chemotherapy.

## PROCEDURE CODES AND BILLING GUIDELINES:

To report provider services, use appropriate CPT\* codes, Alpha Numeric (HCPCS level 2) codes, Revenue codes, and/or diagnosis codes.

- E0766 Electrical stimulation device, used for cancer treatment, includes all accessories, any type
- A4555 Electrode/transducer for use with electrical stimulation device, used for cancer treatment, replacement only

- October 2015 - Annual Review, Policy Revised
- November 2014 - New Policy

Wellmark medical policies address the complex issue of technology assessment of new and emerging treatments, devices, drugs, etc. They are developed to assist in administering plan benefits and constitute neither offers of coverage nor medical advice. Wellmark medical policies contain only a partial, general description of plan or program benefits and do not constitute a contract. Wellmark does not provide health care services and, therefore, cannot guarantee any results or outcomes. Participating providers are independent contractors in private practice and are neither employees nor agents of Wellmark or its affiliates. Treating providers are solely responsible for medical advice and treatment of members. Our medical policies may be updated and therefore are subject to change without notice.

# TUMOR TREATING FIELDS TECHNOLOGY: ALTERNATING ELECTRIC FIELD THERAPY FOR THE TREATMENT OF SOLID TUMORS

LAURA BENSON

**OBJECTIVE:** *To provide an overview of Tumor Treating Fields (TTFields) and the Optune device in the treatment of glioblastoma multiforme as well as discuss the evolution of TTFields technology for the treatment of different tumor types.*

**DATA SOURCES:** *Peer reviewed publications, proceedings, and Internet-based resources.*

**CONCLUSION:** *TTFields represent a unique technological modality for the effective treatment of glioblastoma multiforme and potentially other solid tumors. Oncology nurses are situated to play important roles as educators and advocates for patients and caregivers on the adherent use and management of this new and evolving treatment technology.*

**IMPLICATIONS FOR NURSING PRACTICE:** *The increasing use of TTFields in cancer treatment draws attention to the expanding role for oncology nurses in the administration of this unique therapy. As an educator and advocate, the oncology nurse guides the cancer patient and caregiver through understanding the mechanism of action, initiation of TTFields treatment, and adjusting to the daily challenges of treatment administration, management of side effects, and optimizing compliance to treatment adherence to maximize treatment outcomes.*

**KEY WORDS:** tumor treating fields, TTFields, glioblastoma, tumor treatment.

**T**umor treating fields (TTFields) are a distinct technological modality for the treatment of solid tumors. TTFields therapy is non-invasive, and the therapeutic effect is achieved through the regional delivery of low-intensity, intermediate frequency-specific (100 to 300 kHz), alternating electric fields to the site of a tumor in the body.<sup>1-3</sup> TTFields are generated between opposing ceramic transducers strategically placed directly on the skin on opposite sides to create alternating electric fields through targeted tumor regions. TTFields act with a high degree of specificity on rapidly replicating cancer cells (Fig. 1), exerting disruptive forces on mitotic spindle formation, resulting in mitotic arrest and cancer cell death. TTFields also exert forces on intracellular organelles and macromolecules during cytokinesis, causing abnormal chromosomal segregation and multinucleation, thus further affecting the replication of daughter cells. Components of

rapidly dividing cancer cells that carry a charge are attracted strongly to the alternating electric fields rather than to the weakly charged intracellular components and forces driving cell division. This leads to incomplete mitosis and apoptosis. Quiescent and non-dividing cells are not affected by TTFields.<sup>4-6</sup> The mechanism of action of TTFields is an area of intense research exploring many concepts, such as the role of immunology, migration, and autophagy.<sup>7,8</sup> The data from these studies demonstrate how TTFields therapy targets cancer cells with electric fields tuned to a specific frequency optimized for suppression of cancer cells in different types of solid tumors. Figure 2 shows micrographic images for cells from different tumor types and the optimal frequency for TTFields to suppress proliferation of cells from specific cancer types. Unlike systemic treatment modalities (eg, chemotherapy), TTFields are only active while the alternating electric fields are applied, underscoring the need for vigilant

**FIGURE 1.** TTFields mechanism of action: TTFields act on rapidly dividing cancer cells by disrupting mitotic spindle assembly during metaphase/anaphase. TTFields also produce nonuniform electric fields within cancer cells affecting intracellular organelles and macromolecules during cytokinesis and causing abnormal chromosomal segregation and multinucleation (telophase) effecting further replication of daughter cells.

**FIGURE 2.** TTFields effects on cancer cells are frequency specific.

adherence to TTFields treatment ( $\geq 18$  hours per day is the recommended duration of treatment of glioblastoma multiforme [GBM] for maximal clinical benefit). TTFields are a wearable, portable medical device that are administered by the patient at home. As a regional targeted therapy, with no systemic half-life, TTFields treatment is not associated with systemic adverse effects and therapy can be stopped immediately should a patient experience any issues with treatment. The use of TTFields is unique among other devices in medicine in that the administration of TTFields with the device has a defined therapeutic effect with beneficial clinical outcomes rather than playing a secondary supportive role.

### CLINICAL DEVELOPMENT OF TTFields FOR GBM

The initial evaluation of TTFields therapy in clinical trials was for the treatment of recurrent GBM in the supratentorial region with TTFields applied at a frequency of 200 kHz. GBM tumors are the most common and aggressive brain tumor in adults with a rapid onset of symptoms and a poor prognosis for survival after primary treatment.<sup>9,10</sup> Preliminary pilot studies in recurrent<sup>1</sup> and newly diagnosed GBM<sup>11</sup> demonstrated the viability of TTFields treatment for GBM with a good tolerability profile. Table 1 summarizes the

**TABLE 1.**  
**Summary of TTFields studies of the treatment of GBM**

Recurrent GBM		
Study	Design	Highlighted outcomes
Kirson et al <sup>1</sup>	Phase I – pilot clinical trial – 10 patients with recurrent GBM	Median time to disease progression was 26.1 weeks and median OS was 62.2 weeks. No device-related serious adverse events were reported over 70 months of cumulative treatment in all patients
Stupp et al <sup>3</sup>	Open-label, phase III trial of chemotherapy-free treatment of NovoTTF (20–24 h/day) vs. active chemotherapy. Patients randomized to TTFields alone (n = 120) or active chemotherapy control (n = 117).	Median survival was 6.6 vs. 6.0 months ( $P = .27$ ), 1-year survival rate was 20% and 20%, PFS rate at 6 months was 21.4% and 15.1% ( $P = .13$ ), respectively, in TTFields and active control patients. The TTFields-related adverse events were mild (14%) to moderate (2%) skin rash beneath the transducer arrays
Newly Diagnosed GBM		
Kirson et al <sup>11</sup>	Pilot clinical trial in recurrent and newly diagnosed GBM patients	In newly diagnosed GBM patients, combining TTFields with temozolomide treatment led to a PFS of 155 weeks and OS of 39 + months
Stupp et al <sup>12</sup>	Interim analysis of an open-label, randomized, phase III trial of TTFields in combination with temozolomide for treatment of glioblastoma after initial treatment with chemoradiation	The interim analysis included 210 patients randomized to TTFields plus temozolomide and 105 randomized to temozolomide alone, and was conducted at a median follow-up of 38 months. Median PFS was 7.1 months in the TTFields plus temozolomide group and 4.0 months in the temozolomide-alone group ( $P = .001$ ). Median OS in the per-protocol population was 20.5 months in the TTFields plus temozolomide group and 15.6 months in the temozolomide-alone group (n = 84) ( $P = .004$ ). TTFields plus temozolomide was not associated with any significant increase in systemic toxic effects compared with temozolomide therapy alone
Stupp et al <sup>13</sup>	Full patient analysis set of open-label, randomized phase III trial of TTFields in combination with temozolomide for treatment of glioblastoma after initial treatment with chemoradiation	A total of 695 patients were randomized; the median PFS is 6.7 months for patients in the TTFields plus temozolomide group vs. 4.0 months in the temozolomide-alone group. Median overall survival from randomization is 20.9 months vs. 16 months for the TTFields plus temozolomide and temozolomide alone, respectively ( $P = .00006$ ).

Abbreviations: GBM, glioblastoma multiforme; OS, overall survival; PFS, progression-free survival.

outcomes of studies on TTFields therapy for the treatment of GBM.

The large EF-11 phase III multicenter clinical trial compared the efficacy and safety of TTFields (200 kHz) alone for the treatment of patients with recurrent GBM to patients treated with standard-of-care chemotherapy.<sup>3</sup> The median survival for the TTFields-treated patients was comparable with the standard of care (6.6 months vs. 6 months) and the 1-year survival rate was 20% for both treatment arms. Progression-free survival (PFS) at 6 months was 21% for TTFields compared with 15% for the standard-of-care treatment group. TTFields therapy was found to be as effective as chemotherapy with fewer side effects. Patients in the TTFields monotherapy treatment arm also reported better quality of life with improved cognitive and emotional functioning.<sup>3</sup> Based on the results of this study, TTFields therapy was approved by the US Food and Drug Administration (FDA) in 2011 for use in adults who have recurrent GBM after receiving chemotherapy and whose disease is refractory to surgical and radiation treatment options.

### **TTFIELDS FOR NEWLY DIAGNOSED GBM**

Preclinical data demonstrated that the combined administration of temozolomide (TMZ) and TTFields to human glioma cells in vitro had an additive cytotoxic effect,<sup>1</sup> suggesting the addition of TTFields to TMZ (the standard maintenance therapy for GBM following surgical resection and chemoradiotherapy) would potentially benefit newly diagnosed GBM patients. Based on this hypothesis, a phase III study was initiated in patients with newly diagnosed GBM in the supratentorial region who had completed concomitant standard-of-care chemoradiotherapy. Patients were randomly assigned (2:1) to receive either TMZ combined with TTFields (200 kHz) or TMZ alone. Based on a pre-specified interim analysis of 315 patients demonstrating positive outcome, the trial was terminated early at recommendation of the independent data and safety monitoring committee and the FDA. Patients in the TMZ-alone arm were allowed to cross over to the TMZ-plus-TTFields group. Two thirds of patients in the combined TTFields and TMZ treatment group continued with TTFields treatment after the first tumor progression.<sup>12</sup> The interim analysis demonstrated that adding TTFields to maintenance TMZ significantly prolonged PFS (7.1 months

vs. 4.0 months (hazard ratio, 0.62 [98.7%CI, 0.43–0.89];  $P = .001$ ) and overall survival (OS; 20.5 months vs. 15.6 months) (hazard ratio, 0.64 [99.4%CI, 0.42–0.98];  $P = .004$ ).<sup>12</sup> Based on these results, the FDA approved TTFields for use in combination with TMZ for the maintenance treatment of adult patients with newly diagnosed GBM. Recent results from the analysis of the 5-year full data set (695 patients) confirm the improvements in PFS and OS seen in the interim analysis.<sup>13</sup> The 2- and 5-year survival rates were 43% versus 31% ( $P = .0008$ ) and 13% versus 5% ( $P = .0037$ ) for TTFields plus TMZ versus the TMZ treatment alone group, respectively. Significant improvement in OS was seen for all patient subgroups. TTFields treatment compliance was the only predictor of outcome, with patients who achieved more than 18 hours/day (monthly average) living significantly longer than patients treated for <18 hours/day.<sup>13</sup> The National Comprehensive Cancer Network guidelines recommend TTFields as a standard treatment category 2A option for newly diagnosed GBM in patients with good functional status.<sup>14</sup>

The objectives of this review are to highlight the technology on which TTFields therapy is based, the impact of its use in the treatment of GBM, as well as discuss the potential evolution of TTFields' technology for the treatment of other tumor types.

### **OPTUNE: PATIENT-OPERATED, HOME-USE TTFIELDS DELIVERY SYSTEM**

The first-generation Optune device (Novocure Inc., Portsmouth, NH; formerly known as the NovoTTF-100A System) was designed for TTFields treatment in the home with minimal impact on activities of daily living. A lighter and more compact second-generation device (NovoTTF200A) was approved for use by the FDA in 2016. [Table 2](#) compares both the first- and second-generation devices. Optune is a CE (Conformité Européenne) marked device approved for use in the European Union, Switzerland, Australia, Israel, and Japan for GBM. The second-generation system takes advantage of improvements in electronic components, circuit boards, and digital signaling technology.

The NovoTTF 200A system<sup>15</sup> is comprised of two primary components: the electric field generator (preset to 200 kHz) and insulated transducer arrays. The device treatment kit includes a plug-in power supply, portable battery, battery rack, battery charger, connecting cables, and carrying case (see

**TABLE 2.**

photos comparing the first- and second-generation systems in Table 2). Studies in vitro show that the response of cancer cells to TTFIELDS is directionally dependent with higher inhibitory rates of cell replication in cells dividing perpendicular to the electric field direction.<sup>4</sup> Therefore, the placement of the transducer arrays are designed to maximize the clinical effect of TTFIELDS treatment by utilizing two pairs of transducer arrays that are applied directly to the skin to produce two perpendicular electric fields at a specific frequency for the tumor type. Each pair of transducer arrays creates an electric field that is alternating between positive and negative polarity 200,000 times per second (200 kHz) for GBM, and at every second the fields switch between the two pairs of arrays. This is referred to as a duty cycle.

Each transducer array used to treat GBM lesions within the cranium is composed of nine insulated biocompatible ceramic discs connected to a flexible circuit board and in turn to the electric field generator. The field generator is operated at a frequency of 200 kHz when treating GBM. The discs are arranged in a hypoallergenic adhesive bandage to hold them securely in the proper orientation and are attached directly to the shaved bare skin with an intermediary layer of conductive hydrogel.<sup>16</sup> There are reports of patients experiencing warmth

with the transducer arrays in place and the field generator turned on; for safety, each transducer array has eight temperature sensors that will sound an alarm and shut the device off should the temperature of the array exceed 41°C, which is below the temperature for thermal injury.<sup>16</sup> Integrated device system sensors will sound an alarm in the event of operational and safety issues, such as low battery, loose connectors, overheating of the TTFIELDS generator or the transducer arrays, or poor contact between the transducer and skin surface.

The second-generation TTFIELDS device (including the battery) is smaller and lighter with an overall weight of 2.7 lbs (Table 2) and is designed to be carried more comfortably with improved usability for the patient compared with the first-generation device. The second-generation device was made lighter and smaller using unique digital signal generation technology. Additional technical improvements include: a battery indicator that displays power and alerts patients when to change the battery; a light-detecting sensor that automatically dims the device and charger in darker environments; and features “No-Stop Swap” batteries that allows patients to change batteries or power source without turning off delivery of TTFIELDS treatment. Patient feedback regarding the second-generation device highlights the benefits of

quieter operation and portability. Patients experienced fewer alarms and showed greater adherence using the second-generation device that was maintained or improved in most cases compared with the adherence rates observed with the original device.<sup>17</sup>

Adherence with TTFields treatment is critical for clinical benefit. TTFields are a loco-regional therapy, active only while the electric fields are generated between the transducer arrays and distributed to the site of the tumor. Therefore, the clinical effect is only active when the arrays are in place and the TTField generator is on. In a study of post-marketing surveillance, patients with high daily adherence, defined as  $\geq 75\%$  ( $\geq 18$  hours/day) of average daily adherence with TTFields therapy had a significantly longer OS when compared with patients who fell below the 75% therapy duration.<sup>18</sup> A post-hoc analysis of patient data from a pilot study and a phase III trial also demonstrated improved survival with adherence to longer daily duration of therapy ( $\geq 18$  hours/day)<sup>19,20</sup> and treatment compliance was the only predictor for long-term patient survival in the full analysis of the EF-14 trial patient data set.<sup>21</sup>

As monotherapy for recurrent GBM, TTFields in the EF11 study was associated with improvement

in patient-reported assessments of cognitive and social functioning when compared with standard-of-care chemotherapy and symptom scale analysis showed an increase in treatment-associated toxicity directly related to the chemotherapy regimen, such as pain and fatigue that was not reported for patients in the TTFields treatment group,<sup>3,22</sup> suggesting quality of life benefits with TTFields treatment.

In addition to adherence, optimal placement of the transducer arrays may account for improved clinical outcomes. State-of-the-art technological research using modeling and simulations have demonstrated that changing the transducer array placement on the skin to address specific tumor locations results in substantial increases in the induced field intensity within the tumor (Fig. 3), supporting individualized treatment planning for GBM patients.<sup>23</sup> The NovoTAL System is an algorithmic software program validated by a user study group that optimizes transducer array layouts for an individual GBM patient based on head size and tumor location using measurements obtained from magnetic resonance imaging (MRI) data.<sup>24</sup> The algorithm will derive the optimal paired transducer array configuration to deliver the highest intensi-

FIGURE 3. Transducer array placement influences TTFields intensity distribution. Simulation studies demonstrate the effect of array placement on electric field intensities across brain tissue. The objectives of such studies are to ensure optimal TTFields intensity at the site of the tumor.<sup>23</sup>

ty of TTFields to the site of a tumor (Fig. 4). The NovoTAL System was approved by the FDA in 2013.<sup>25</sup> The Optune device uses preset treatment levels for frequency (200 kHz for GBM) and a minimal field intensity of 0.7 V/cm across the brain tissue and site of the tumor.<sup>16,26</sup> Follow-up MRI imaging is regularly performed after TTFields therapy is started to track treatment effect and rule out recurrence.<sup>19</sup> In patients with recurrent GBM, 44% of GBM tumors that respond to TTFields treatment initially showed growth before shrinking in size after a median of 4 months with continuous TTFields therapy.<sup>19</sup> A series of case studies presented by Turner et al<sup>27</sup> show evidence for “out-of-field” tumor recurrence potentially because of suboptimal field intensity at the margins of the resected tumor bed. The observations imply that “re-mapping” the transducer array placement based on a change in follow-up MRI, may be an effective strategy to pre-emptively target tumor recurrence.

There are a few important contraindications and warnings associated with using the Optune system for the indicated treatment of either recurrent or newly diagnosed adults with GBM. The device should not be used in patients with active implanted medical devices (ie, deep brain stimulators, vagus nerve stimulators, pacemakers, or defibrillators), skull defects, or bullet fragments.<sup>15</sup> In the United States the FDA requires that the device must be prescribed by a health care provider who has completed certification training provided by Novocure.<sup>15</sup> Optune is classified as durable medical equipment and is typically covered under a patient’s medical benefit with commercial insurance companies. Optune is covered by most commercial insurance companies under published coverage policy or through case-by-case review.

#### PATIENT AND CAREGIVER EDUCATION TO OPTIMIZE TTFIELDS DELIVERY

A GBM patient’s social, cognitive, and physical statuses all play a role in determining whether the patient is a good candidate for TTFields therapy. Patients with physical and cognitive impairment and lacking good daily support are not likely to achieve the recommended adherence goals that are optimal for clinical benefit. Ideally, a patient should have at least one support person who can assist the patient if needed. This is to assist with device alarms, adverse events, and help with removing and

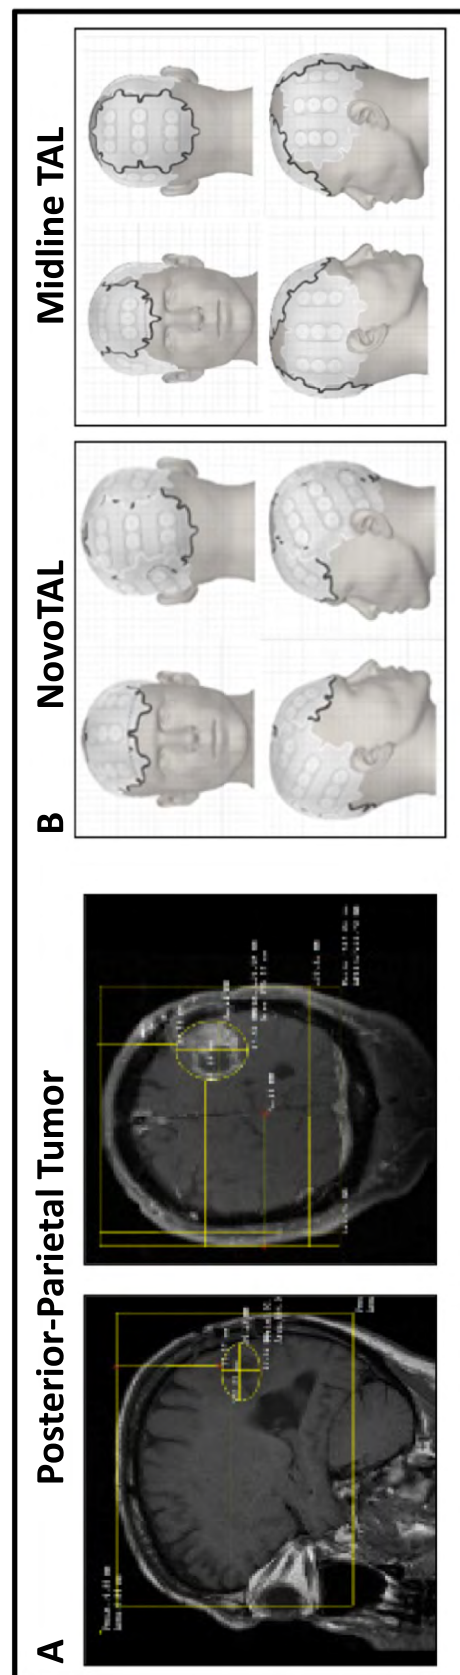

FIGURE 4. NovoTAL treatment planning. (A) Representative NovoTAL treatment planning performed on MRI sagittal and axial T1 post-contrast sequences of a posterior-parietal tumor. (B) Corresponding array layout generated using the NovoTAL System (left) and symmetric midline array configuration for the same tumor (right).<sup>24</sup>

accurately replacing the arrays as part of the normal treatment with TTFields.<sup>28</sup>

Patient and caregiver education are an essential part of TTFields treatment. Each should have a basic understanding of the mechanism of action, the components of the Optune system, how they work, and the importance of meeting treatment adherence goals.<sup>17,29</sup> Patients and caregivers are provided with training in advance of starting therapy with TTFields. This training includes instructions in caring for and maintaining the system components, managing system alarms, and how to prevent and manage skin irritation. Throughout training and follow-up, the importance of adherence to therapy is emphasized.

In general, patients are instructed to replace the transducer arrays at least every 4 days,<sup>28</sup> to reshuffle the scalp, and reapply new transducer arrays. Some patients may require more frequent array changing and reshuffling. Used transducers and other system parts are returned for proper disposal. The time period for array replacement depends on individual hair growth, rates of sweating, activity level, and weather.<sup>29</sup> Both the first- and second-generation devices are portable so that patients can participate in activities of daily living with minimal inconvenience (Fig. 5). The redesigned second-generation device is currently used by patients receiving treatment for GBM. The first-generation device is currently used in ongoing investigations in other tumor types delivering therapy at different frequencies. It is also important to note that TTFields therapy poses no danger to anyone in close proximity to the patient. The health care team including nurses supporting the patient and caregiver can help develop strategies to minimize the intru-

**FIGURE 5.** Portability of the Optune device allows patients to participate in activities of daily living. (Photo with permission from the patient.).

sion of TTFields therapy and the device on daily activities. Strategies include selecting wigs and hats if the patient wants to disguise the transducer arrays when out in public. Because restrictive or tightly woven wigs or hats will trap heat and effect device operation, selecting scarves, loosely woven or ventilated wigs appropriately sized for the patient will dissipate heat more effectively while covering the arrays.<sup>29</sup> The cables connecting the power supply and field generator to the transducer array can be arranged under selected layers of clothing to make them less obvious and intrusive.

The device is designed to assist the patient, caregiver, and health care team achieve optimal device-wear time goals. A patient-specific compliance report, compiling daily use times is generated monthly to track the percentage of active TTFields delivered over a 24-hour period. The reports provide tangible evidence for review with the patient and caregiver to help identify issues with adherence so

**FIGURE 6.** Examples of contact dermatitis reactions related to long-term TTFields treatment. Erythema from scalp irritation associated caused by adhesive or hydrogel is shown in the upper panel. The lower panel shows an irritant reaction with erythema associated with the hydrogel between the transducer arrays and the scalp.<sup>16</sup>

that strategies can be adopted to improve treatment duration and potentially improve clinical response.<sup>29</sup> Novocure provides device support specialists trained to assist patients and caregivers with the daily operation of the system.<sup>28</sup> The patient's device support specialist provides comprehensive training and counseling to the patient on the operation of the Optune device and guidance on specific placement of the transducer arrays. The device support specialist also downloads the monthly adherence report, which is provided to the health care team. This is a valuable tool to monitor the patient time on therapy, to reinforce teaching, and to provide coaching on an ongoing basis. The monthly report provides a mechanism to assist with achieving optimal treatment adherence goals.<sup>28</sup> The entire health care team utilizes the data available from the Optune system, along with the full spectrum of clinical data, including MRI imaging, to make the required clinical decisions to optimize treatment outcomes for each patient.

The most common adverse events related to the use of either the first- or second-generation device are scalp irritation and headache.<sup>3,12</sup> These

events are usually mild to moderate in severity and occur below the transducer array and adhesive bandage. Dermatologic adverse events fall into the following categories: irritant contact dermatitis caused by sweat, hydrogel, and/or alcohol; allergic contact dermatitis from a delayed type hypersensitivity reaction to the array adhesive or hydrogel; mechanical erosions from cuts from shaving or removal of the arrays; ulcers caused by inhibited perfusion as a result of the arrays pressing on the skin; and bacterial skin infections.<sup>16</sup> Examples of contact dermatitis reaction-related TTFIELDS treatment are shown in Figure 6. Adequate skin preparation is essential for effective contact between the array transducer and skin, and good scalp hygiene and array placement are critical components of maintaining long-term skin integrity.<sup>28</sup> Effective strategies for preventing and managing skin irritation are summarized in Table 3. Most dermatologic adverse events can be managed with topical treatments and slight adjustment of the transducer arrays to minimize skin irritation.<sup>16</sup> A treatment algorithm for managing dermatologic adverse events is shown in Figure 7.

**TABLE 3.**  
Preventive strategies for dermatological adverse events related to Optune TTFIELDS treatment<sup>16,29</sup>

Category	Guidelines for patient and caregiver
Shaving and preparation of the scalp	<ul style="list-style-type: none"> <li>• An electric shaver is recommended, having a lower risk to cause cuts compared with a razor</li> <li>• Proper hand washing prior to preparing the scalp for array application</li> <li>• Take time shaving the scalp using gentle but firm circular motions</li> <li>• Ensure a close shave before applying the arrays</li> <li>• Cleaning the electric razor after every shave is important to lessen the risk of skin infection</li> <li>• Wash scalp with fragrance-free, mild shampoo (eg, baby shampoo); seborrheic dermatitis shampoo can also be used as it has antibacterial properties (eg, pyrithione zinc 2%, ciclopirox 1%, ketoconazole 2%)</li> <li>• Ensure scalp is completely dry before applying a new set of arrays</li> </ul>
Use of isopropyl (70%) alcohol	<ul style="list-style-type: none"> <li>• Use of first aid antiseptic rubbing alcohol (70% isopropyl alcohol) prior to array application is a necessary step to remove naturally occurring scalp oils, resulting in better adherence of the arrays to the scalp</li> <li>• After shaving and before placing the arrays, wipe the scalp with a gauze or cotton ball soaked in first aid antiseptic rubbing alcohol (70% isopropyl alcohol)</li> <li>• Avoid areas of skin irritation, as the first aid antiseptic rubbing alcohol (70% isopropyl alcohol) may further irritate the skin</li> </ul>
Transducer array exchanges	<ul style="list-style-type: none"> <li>• Change arrays on a regular basis (at least every 3–4 days)</li> <li>• When removing the arrays, avoid “pulling” on the skin; take approximately 60 sec to remove each array</li> <li>• Use of mineral (baby) oil on the edges of the array may make removal of the adhesive tape easier and less irritating to the skin</li> <li>• To remove leftover array adhesive, use gauze or a cotton ball soaked in mineral (baby) oil or pour oil into hands and gently rub scalp in areas of remaining adhesive</li> <li>• Pay close attention to the scalp at each array exchange, and notify the doctor or nurse if there are signs of skin irritation or open areas, to receive information on how to treat them; taking a picture of the affected areas on the scalp and sharing it with the doctor or nurse is advised</li> </ul>

Type of Dermatologic Adverse Event and Recommended Interventions				
Severity	Dermatitis	Erosions	Infections	Ulceration
Preventive	Patient and caregiver education; shifting of transducer arrays; regular (every three to four days) changing of the transducer arrays; close attention to the condition of the skin at time of array exchange and open communication with the healthcare team related to any erythema or irritation; hand washing prior to array exchange to minimize risk of infection; avoiding placement of ceramic discs immediately over screws, wires, or scars; proper ventilation when covering arrays (e.g., ventilated wigs or caps, lightweight scarves)			
<b>For all grades:</b> Advise patients not to place array discs directly over affected area(s) when exchanging arrays. Assess how often the patient is doing an array exchange. Reassess after two weeks (either by healthcare provider or patient self-report). If reaction worsens or does not improve, proceed to guidance for next grade.				
Grade 1	High-potency topical corticosteroid ointments (e.g., clobetasol)	Topical antibiotics (e.g., mupirocin or bacitracin ointment)	Culture, then treat with appropriate topical antibiotic.	Open areas require topical antibiotics.
<b>For grade 1:</b> Reassess after two weeks (either by healthcare provider or patient self-report). If reaction worsens or does not improve, proceed to guidance for next grade.				
Grade 2	High-potency topical corticosteroid ointments and avoidance of direct contact of discs and adhesive tape with affected area(s)	Topical and oral antibiotics and avoidance of direct contact of discs and adhesive tape with affected area(s)	Culture, then treat with appropriate oral antibiotic; avoid direct contact of discs and adhesive tape with affected area(s).	Topical and oral antibiotics and avoidance of direct contact of discs and adhesive tape with affected area(s)
<b>For grade 2:</b> Reassess in two weeks. Consider resuming tumor-treating fields therapy once event has recovered to grade 1.				
Grade 3	Treatment interruption; consider dermatology consultation.	Treatment interruption; consider dermatology consultation.	Obtain skin culture; oral antibiotics; consider treatment interruption until grade 1; consider dermatology consultation.	Treatment interruption; consider dermatology consultation.

FIGURE 7. Treatment algorithm for dermatologic adverse events associated with the use of Optune therapy.<sup>16</sup>

### FUTURE TUMOR TARGETS FOR TTFields

Preclinical studies demonstrate that the optimal anti-proliferative effect of TTFields on isolated cancer cells is dependent on the frequency of the electric fields that is specific to the source of the isolated tumor cells.<sup>4,6,30,31</sup> Therefore, in the clinical setting, TTFields administration is applied at 200 kHz for GBM, representing the frequency with the greatest reduction in glioma cell proliferation<sup>1</sup> and at a frequency of 150 kHz for non-small cell lung cancer cells in vitro.<sup>6,30</sup> TTFields treatment effect is also dose-dependent, where “dose” is equated with the peak-to-peak alternating electric field intensity, which has a minimal threshold value of 1 V/cm. Below this value there is little effect on cancer cell proliferation.<sup>1,4,6,29</sup> Clinical development is currently underway for brain metastases from lung cancers (150 kHz), non-small cell lung

cancer (150 kHz), ovarian cancer (200 kHz), pancreatic cancer (150 kHz), and mesothelioma (150 kHz).<sup>32,33</sup> Details regarding these phase II/III studies are summarized in Table 4. Preclinical studies are ongoing in the following cancer types; breast, cervical, colorectal, gastric, hepatocellular, melanoma, renal, urinary transitional cell and small cell lung cancer.

Radiation therapy (RT) is integral in the standard of care for GBM and other tumor types and targeted immunotherapies are evolving as viable treatment options for a variety of cancers. Preclinical studies suggest that there are synergistic effects for the combination of TTFields with RT and immunotherapies. TTFields administered before RT exposure sensitize glioma cell lines to RT damage and increase antimitotic activity through inhibition of cell survival, cell cycle regulation, and DNA repair activity.<sup>34,35</sup> These results suggest that clin-

**TABLE 4.**  
**Ongoing TTFIELDS clinical trials for cancer<sup>33</sup>**

Tumor type	Study name	Full title	Registration number	TTFIELDS frequency
Brain metastases secondary to NSCLC	COMET	A phase II randomized study of TTFIELD therapy (150 kHz) versus supportive care in non-small cell lung cancer patients with 1–5 brain metastases following optimal standard local treatment	NCT01755624	150 kHz
Ovarian carcinoma	INNOVATE	An open label pilot study of the NovoTTF-100L(O) system (NovoTTF Therapy) (200 kHz) concomitant with weekly paclitaxel for recurrent ovarian carcinoma	NCT02244502	200 kHz
NSCLC	LUNAR	Pivotal, randomized, open-label study of tumor treating fields (TTFIELDS) (150 kHz) in combination with PD-1 inhibitors or docetaxel, for second line treatment of non-small cell lung cancer (NSCLC)	NCT02973789	150 kHz
Brain metastases secondary to NSCLC	METIS	Pivotal, open-label, randomized study of radiosurgery with or without tumor treating fields (TTFIELDS) (150 kHz) for 1–10 brain metastases from non-small cell lung cancer (NSCLC)	NCT02831959	150 kHz
Pancreatic adenocarcinoma	PANOVA	A phase II study of TTFIELDS (150 kHz) concomitant with gemcitabine and TTFIELDS concomitant with gemcitabine plus Nab-paclitaxel for front-line therapy of advanced pancreatic adenocarcinoma	NCT01971281	150 kHz
Mesothelioma	STELLAR	A phase II trial of pemetrexed and cisplatin or carboplatin in combination with TTFIELDS (150 kHz) as first-line treatment in malignant pleural mesothelioma	NCT02397928	150 kHz

ical trials of TTFIELDS in combination with RT should be considered because the combination may improve the clinical benefit of RT. Early evidence suggests that TTFIELDS combined with an immune check point inhibitor (anti-PD-1) augments immunogenic cell death and that combining TTFIELDS with cancer immunotherapies may enhance tumor control.<sup>36</sup> Ongoing research suggests that there are potential complementary or synergistic effects when TTFIELDS are added to chemotherapies or immunotherapies. Localized, regional therapy with TTFIELDS may provide tumor control in combination with therapies having synergistic mechanisms of action without dose-limiting toxicity or compounding any potential adverse effects associated with the systemic treatment. The FDA recently (May 2017) issued a humanitarian use device designation for TTFIELDS for the treatment of pleural mesothelioma, potentially leading to a Humanitarian Device Exemption approval in the United States.

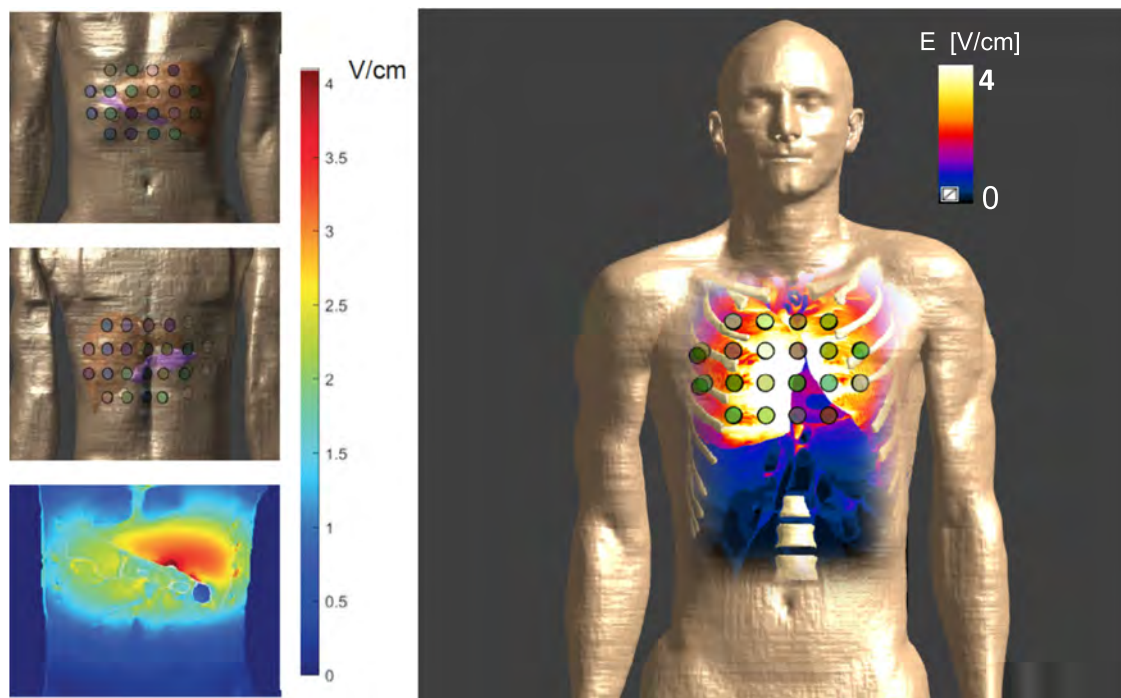

The evolving use of TTFIELDS for tumors in different parts of the body creates technological challenges regarding the design and application of the transducer arrays that deliver therapeutic in-

tensities of TTFIELDS to the site of the tumor and optimize therapeutic outcomes for the patient.<sup>37,38</sup> Digital phantom models (Fig. 8) and simulation analysis demonstrate that effective field intensities can be administered to target tumors in the thorax and abdomen. Typically the number, size, and arrangement of the transducer arrays for tumor treatment in the thorax and abdomen are larger than those used for cranial placement in the treatment of GBM. These parameters along with transducer array placement and arrangement within an array are factors integrated into simulation studies to optimize TTFIELDS delivery to new tumor types and other regions of the body.

#### IMPLICATIONS FOR ONCOLOGY NURSING PRACTICE

The increasing investigational use of TTFIELDS in cancer treatment and the use of the Optune system for the treatment of GBM draw attention to the expanding role for oncology nurses in the

**FIGURE 8.** Calculated electric field intensity in the thorax when TTFields are applied to a male computational phantom model. Simulations demonstrate that optimized array placement can result in delivery of TTFields to treat tumors in the abdominal (right) and thoracic (left) cavities.<sup>37,38</sup>

administration of this emerging therapy. The use of TTFields represents a choice for a different and distinct additional therapeutic modality to consider when treating solid tumors. The best clinical outcomes for TTFields treatment are equated with good daily patient adherence ( $\geq 18$  hours/day). Oncology nurses will play an important role in coaching both the patient and caregiver toward realizing this daily goal. Strategies to maximize adherence and to minimize adverse effects and their severity with prevention and treatment tips are a crucial part of the nursing role in the daily management of TTFields treatment. The importance of compliance should be strongly conveyed to patients by oncology nurses and treating physicians. Most recent reports suggest that patients with compliance over 90% had a median survival of 24.9 months (28.7 months from diagnosis) and a 5-year survival of

29.3%.<sup>39</sup> As an educator, navigator and advocate, the oncology nurse guides the cancer patient and caregiver in decision making, through initiation of TTFields therapy and adjusting to the daily challenges of treatment administration to optimize adherence and treatment outcomes.

### CONCLUSION

TTFields and Optune represent a unique technological modality using a non-invasive at-home device for the effective treatment of GBM and cancerous tumors. Oncology nurses are situated to become important educators and advocates for the patient and caregiver on the adherent use and management of this new and evolving treatment technology.

## A MESSAGE FROM ASCO'S PRESIDENT

I remember when ASCO first conceived of publishing an annual report on the most transformative research occurring in cancer care. Thirteen reports later, the progress we have chronicled is remarkable, and this year is no different. The research featured in ASCO's *Clinical Cancer Advances 2018* report underscores the impressive gains in our understanding of cancer and in our ability to tailor treatments to tumors' genetic makeup.

The ASCO 2018 Advance of the Year, adoptive cell immunotherapy, allows clinicians to genetically reprogram patients' own immune cells to find and attack cancer cells throughout the body. Chimeric antigen receptor (CAR) T-cell therapy—a type of adoptive cell immunotherapy—has led to remarkable results in young patients with acute lymphoblastic leukemia (ALL) and in adults with lymphoma and multiple myeloma. Researchers are also exploring this approach in other types of cancer.

This advance would not be possible without robust federal investment in cancer research. The first clinical trial of CAR T-cell therapy in children with ALL was funded, in part, by grants from the National Cancer Institute (NCI), and researchers at the NCI Center for Cancer Research were the first to report on possible CAR T-cell therapy for multiple myeloma. These discoveries follow decades of prior research on immunology and cancer biology, much of which was supported by federal dollars.

In fact, many advances that are highlighted in the 2018 *Clinical Cancer Advances* report were made possible thanks to our nation's support for biomedical research. Funding from the US National Institutes of Health and the NCI helps researchers pursue critical patient care questions and addresses vital, unmet needs that private industry has little incentive to take on. Federally supported cancer research generates the biomedical innovations that fuel the development and availability of new and improved treatments for patients. We need sustained federal research investment to accelerate the discovery of the next generation of cancer treatments.

Another major trend in this year's report is progress in precision medicine approaches to treat cancer. Although precision medicine offers promise to people with cancer and their families, that promise is only as good as our ability to make these treatments available to all patients. My presidential theme, "Delivering Discoveries: Expanding the Reach of Precision Medicine," focuses on tackling this formidable challenge so that new targeted therapies are accessible to anyone who faces a cancer diagnosis. By improving access to high-quality care, harnessing big data on patient outcomes from across the globe, and pursuing innovative clinical trials, I am optimistic that we will speed the delivery of these most promising treatments to more patients.

Sincerely,

Bruce E. Johnson, FASCO

ASCO President, 2017 to 2018

## EXECUTIVE SUMMARY

Approximately 1.7 million people received a cancer diagnosis in the United States in 2017.<sup>1</sup> Today, more than 15 million Americans, nearly

one in 20, is a survivor of cancer, which means that they have had or are living with cancer.<sup>2</sup> The number of survivors is growing steadily; experts estimate that there will be 26 million by 2040, with 73% 65 years of age or older.<sup>3</sup>

## ASSOCIATED CONTENT

Appendix  
DOI: <https://doi.org/10.1200/JCO.2017.77.0446>

DOI: <https://doi.org/10.1200/JCO.2017.77.0446>

At the same time, the rate of cancer death has been decreasing, and people are living longer with cancer than ever before. Approximately 64% of US patients diagnosed with cancer in 2005 have lived 10 years or more beyond diagnosis, up from 35% for those diagnosed in 1975.<sup>4</sup>

These trends reflect our and other nations' investments in cancer research and the relentless efforts to advance discovery and care. The volume and pace of cancer research is growing rapidly. For example, the number of medical journal articles with the word "cancer" in the title quadrupled in the last decade, from approximately 28,000 in 2007 to 120,000 in 2017.

Yet more work lies ahead. Because of the aging and growing population, there will be more new patients with cancer every year, both in the United States and worldwide. For every life saved, there are still many people waiting for the next breakthrough for themselves or their loved ones.

This report highlights the most important clinical advances of 2017 and previews where cancer science is headed. New treatments help patients with melanoma and ovarian, lung, bladder, brain, and prostate cancer live longer, and many other new therapies delay cancer worsening or lower the chance of recurrence.

In the span of just 1 year—from November 2016 through October 2017—the US Food and Drug Administration (FDA) approved 31 new therapies for > 16 types of cancer. Among the new approvals are two firsts: an adoptive cell immunotherapy—the ASCO Advance of the Year—and a tumor agnostic therapy, that is, treatment that works against different types of cancers that share a common genetic abnormality.

### **First Adoptive Cell Immunotherapy and Gene Therapy for Cancer**

In August 2017, the FDA approved the first adoptive cell immunotherapy, also known as chimeric antigen receptor (CAR) T-cell therapy, and the first gene therapy for cancer, tisagenlecleucel. This double first approval stems from decades of research on how to train the patient's own immune cells to fight cancer.

Even more important than the historic significance of this achievement is the medical need this unique new therapy is poised to fill. Tisagenlecleucel may be the first treatment to truly turn the tables on recurrent pediatric acute lymphoblastic leukemia (ALL), one of the most common cancers in children. In a clinical trial, cancer in four of five patients went into remission after treatment, which was custom prepared in the laboratory from the patients' own blood cells.

In October 2017, the FDA approved the second CAR T-cell therapy, axicabtagene ciloleucel, to treat adults with certain types of lymphoma. Other CAR T-cell therapies seem promising in clinical trials of people with multiple myeloma. CAR T-cell therapy represents an exciting innovation that has the potential to transform cancer care. It also raises the ongoing issue of cost and reminds us that, as a community, we need to find solutions that will assure that every patient with cancer has access to the care they need. See *Advance of the Year: Adoptive Cell Immunotherapy* for more about these advances.

### **Precision Oncology**

The other historic first among FDA approvals in 2017 marks a milestone in precision oncology. The immune checkpoint

inhibitor pembrolizumab became the first cancer treatment to receive a tumor-agnostic indication. It received accelerated approval to treat any type of solid tumor that has mismatch repair deficiency, a defect that undermines the cell's ability to repair DNA damage. This approval provides patients with a wide range of different cancers an effective way to control the disease.

Another promising treatment, larotrectinib, which homes in on a different, rare genomic abnormality in the tumor known as tropomyosin receptor kinase (*TRK*) gene fusion, also seems to work across tumor types and in both adults and children. Larotrectinib has the potential to become the first tumor-agnostic targeted therapy for cancer.

Meanwhile, fundamental cancer biology research is uncovering new molecular pathways that are being explored as potential therapeutic targets. In 2017 alone, the FDA approved > 13 new targeted medicines for people with leukemia and multiple myeloma, as well as ovarian, breast, and lung cancer.

### **Targeted Agent and Profiling Utilization Registry Study**

In 2017, ASCO's Targeted Agent and Profiling Utilization Registry (TAPUR) Study ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02693535) identifier: NCT02693535) continued expanding. As of November 2, 2017, there were > 495 participants enrolled on a study drug at more than 83 sites in 18 states, each offering 17 different targeted therapy options provided by the seven participating pharmaceutical companies.

In addition, the study protocol was revised to lower the age of eligibility for the trial from 18 years to 12 years to extend the opportunity for participation to adolescent patients with advanced cancer in cases in which there is a defined adolescent dose for the study drugs.

The objective for the TAPUR Study is to evaluate molecularly targeted cancer drugs and collect data on clinical outcomes to learn about additional uses of these drugs outside of the indications already approved by the FDA.

The TAPUR Study is registered with a full list of inclusion and exclusion criteria and other information. Prospective patients, researchers, and practices interested in participating can visit the TAPUR website, [TAPUR.org](https://TAPUR.org), or e-mail the TAPUR Study team at [TAPUR@asco.org](mailto:TAPUR@asco.org).

### **Patient-Centered Care**

As life expectancy after a cancer diagnosis continues to improve, there is growing recognition of the need to address patients' emotional and psychosocial needs from the time of diagnosis through treatment and survivorship. *Clinical Cancer Advances 2018* highlights efforts to preserve patient quality of life by avoiding unnecessary treatment or by lowering therapy dose or duration. Furthermore, new tools that engage patients in their own care, such as Web programs for symptom monitoring, psychological support,

and end-of-life planning, are showing benefits for both patients and health care systems.

Finally, we are entering a new era in care in which biomedical research is no longer solely driven by researchers and physicians, but also by patients who are more and more directly engaged in driving progress forward. By donating tissue samples and clinical information, or by helping to design research studies and formulate practice guidelines, patients are providing valuable perspectives and contributing to better care for other patients now and in the future.

### **Federal Support for Cancer Research Is Critical**

Federally funded cancer research has driven many of the major prevention and treatment advances of the past 50 years, and has led to substantial improvements in patient survival and dramatic improvements in quality of life for people with cancer. The National Cancer Institute (NCI) funds studies in areas that private industry has little incentive to address, such as research on cancer prevention, screening, and rare cancers, as well as groundbreaking foundational research.

The US National Institutes for Health (NIH) is the single largest public funder of biomedical research in the world. Federally funded biomedical research helps keep the United States globally competitive by contributing \$65 billion in economic growth, supporting 380,000 jobs, and generating 2.21 dollars in local economic growth for every dollar in NIH funding.<sup>5,6</sup> It is estimated that NIH-funded basic research provides a positive return to public investment of 43%.<sup>7</sup>

Research funded by the NIH also fuels the innovation on which companies depend to bring new treatments to the marketplace, helping make the United States the global leader in developing treatments. Studies show that NIH investments in biomedical research stimulate increased private investment: Every dollar of increase in public clinical research stimulates 2.35 dollars of industry investment at 3 years.<sup>7</sup>

#### **Cancer Research Funding**

More than nine in 10 Americans (91%) believe that the US government should dedicate substantial funding to diagnose, prevent, and treat cancer. Nearly three in four Americans (73%) say the government should spend more to develop cancer treatments and cures, even if it means higher taxes or adding to the deficit (ASCO's National Cancer Opinion Survey, 2017).

Funding from the NIH and other federal agencies supported > 25% of the top advances featured in this report. Among the most notable are studies that have found:

- Prolonged survival with new approaches:
  - A new treatment regimen helps women with recurrent ovarian cancer live longer.
  - A Web-based tool for self-reporting symptoms during chemotherapy helps patients with advanced cancer live longer.

- Longer hormone therapy reduces the risk of breast cancer recurrence.
- Reduced adverse effects with less treatment:
  - Shortening the duration of adjuvant chemotherapy for stage III colorectal cancer is safe and reduces adverse effects.
  - In patients with melanoma, less extensive surgery lowers the risk of lymphedema without compromising survival.
  - Lowering the radiation dose for oropharyngeal cancer reduces health complications without compromising survival.
- Effective strategies to help patients with advanced cancer understand and cope with their prognosis.
- For cancer-related fatigue, exercise and psychological support are more effective than medication.
- New insights on the adverse effects of certain prostate cancer and lung cancer treatments will help inform treatment and survivorship discussions.

In the last year, Congress has made critical investments to improve and accelerate cancer research through supplemental funding for the Cancer Moonshot Initiative and the 21st Century Cures Act. In addition, Congress included a boost in funding for NIH and NCI in fiscal year 2017; however, despite these funding increases, NCI's budget, when adjusted for inflation, remains below prerecession levels<sup>8</sup> (Fig 1).

One manifestation of this reduced budget is that it is more difficult for researchers to secure funding. For example, in 2015, only 16% of new research proposals received funding compared with 27% in 2001.<sup>9</sup> This decline in funding means that it is more difficult for the field to recruit and retain young researchers, which threatens future progress against cancer. Flat funding and budget cuts translate into less innovation, fewer studies launched, fewer patients enrolled in clinical trials, fewer researchers entering the field, and fewer discoveries.

Predictable funding increases are critical to sustain progress against cancer. Dependable and robust funding is essential for planning and conducting multiyear trials that advance new treatments.

#### **A Call to Action to Congress**

Americans are counting on our leaders to invest in biomedical innovation that will deliver the next generation of cancer cures to patients. ASCO urges Congress to give hope to millions of Americans with cancer by continuing to build on its investment in cancer research and providing predictable funding increases to NIH and NCI.

### **About Clinical Cancer Advances**

ASCO develops this annual report, now in its 13th edition, to outline the progress that has been achieved in clinical cancer research and care each year. As a whole, *Clinical Cancer Advances* highlights current trends in the field and previews future directions of cancer research.

The content of this report was developed under the direction of a 20-person editorial board composed of experts in a wide range

# FEDERAL FUNDING IS CRITICAL TO ADVANCING OUR NATION'S CANCER PROGRESS

People with cancer are living better and longer, thanks to our nation's investment in cancer research

▼ **25%**

**DECLINE IN CANCER DEATH RATE**

Since a peak in 1991<sup>1</sup>

**110+**

**NEW CANCER DRUGS OR INDICATIONS APPROVED BY THE FDA SINCE 2006<sup>2</sup>**

**INCREASED 5-YEAR SURVIVAL**

2 out of 3 people with cancer live at least 5 years after diagnosis<sup>1</sup>

▲ **15.5M**

**CANCER SURVIVORS**

Up from 11.4 million in 2006<sup>1</sup>

NCI's budget, when adjusted for inflation, remains below prerecession levels<sup>3</sup>

**Congress needs to build on its investment**

NIH = National Institutes of Health NCI = National Cancer Institute

<sup>3</sup>Figures do not include additional funding from the 21st Century Cures Act.

Source: National Cancer Institute

**Increased federal funding is urgently needed to accelerate life-saving research and new cancer breakthroughs<sup>4,5</sup>**

**EXPANDED PREVENTION AND DETECTION STRATEGIES**

Boost prevention research and increase testing to identify high-risk patients

**PRECISION MEDICINE AND IMMUNOTHERAPY RESEARCH**

Support mechanisms to identify, test and validate new predictive biomarkers

**ENHANCED DATA SHARING**

Create a national ecosystem for sharing and analyzing data

**Millions of Americans living with cancer and their loved ones are waiting for new breakthroughs**

**ASCO calls on Congress to build on critical investments by increasing funding to the NIH and NCI.**

of cancer types, as well as surgical oncology, radiation oncology, cancer prevention and screening, quality of care, health disparities, tumor biology, and developmental therapeutics. The editors reviewed scientific literature that was published in peer-reviewed journals or presented at major medical conferences from October 2016 through September 2017 and selected advances according to formal criteria. Primarily, advances must improve meaningful patient outcomes, such as survival or quality of life, and have a strong scientific impact.

### About ASCO

Founded in 1964, ASCO is committed to making a world of difference in cancer care. As the world's leading organization of its kind, ASCO represents > 40,000 oncology professionals who care for patients living with cancer. Through research, education, and the promotion of the highest-quality patient care, ASCO works to conquer cancer and create a world in which cancer is prevented or cured and every survivor is healthy. ASCO is supported by its affiliate organization, the Conquer Cancer Foundation. Learn more at [www.ASCO.org](http://www.ASCO.org); explore patient education resources at [www.Cancer.Net](http://www.Cancer.Net); and follow us on Facebook, Twitter, LinkedIn, and YouTube.

### Join Us: Tell Your Representatives to Support Cancer Policy Priorities

More than 100 ASCO members from across the country came to the US capitol in September 2017 for ASCO's annual Advocacy Summit, where members urged Congress to support issues critical to improving cancer research and care. During meetings with members of Congress and staff, ASCO members asked Congress to support policies to increase federal research funding, ensure access to chemotherapy services for patients enrolled in Medicare, and improve the affordability of cancer drugs.

ASCO members have an opportunity to make their voices heard throughout the year by engaging with their members of Congress on key issues related to cancer policy. To learn more about participating in ongoing advocacy efforts, visit [asco.org/ACTNetwork](http://asco.org/ACTNetwork).

### The Conquer Cancer Foundation

The Conquer Cancer Foundation was created by the world's foremost cancer physicians of ASCO to seek dramatic advances in the prevention, treatment, and cure of all types of cancer. Toward the vision of a world free from the fear of cancer, Conquer Cancer works to conquer this disease by funding breakthrough cancer research and sharing cutting-edge knowledge with patients and physicians worldwide, and by improving the quality of care and access to care, enhancing the lives of all who are touched by cancer.

Over 34 years, > \$109 million in funding has been provided through Conquer Cancer's Grants and Awards Program to support clinical and translational scientists, at all levels of their careers and working around the globe, to address the full spectrum of oncology, from prevention through survivorship and end-of-life care.

The foundation has given > 1,800 grants and awards in 71 countries. Conquer Cancer grants have helped researchers launch successful careers and make discoveries that benefit patients with cancer.

One of the top patient care advances featured in this report was made possible by funding from Conquer Cancer (see *Patient Engagement Leads to Improved Care*), and several other studies that are highlighted were led by past Conquer Cancer grant recipients who have continued their careers in oncology research.

This report was supported, in part, by funds from Conquer Cancer's Mission Endowment.

### ADVANCE OF THE YEAR: ADOPTIVE CELL IMMUNOTHERAPY

This year, ASCO named adoptive cell immunotherapy as the clinical cancer Advance of the Year. After decades of research, this powerful and decidedly unique way of treating cancer has become available to certain patients with an otherwise incurable blood cancer.

### What Is Adoptive Cell Immunotherapy?

Immune cells navigate the body looking for anything that does not belong—bacteria, viruses, and even cancer cells. They do so by using their molecular feelers, or receptors, to scan for foreign molecules that intruder cells display on their surface. Once an intruder is detected, a class of immune cells, known as cytotoxic T cells, move in to eliminate it.

Unfortunately, cancers have a number of ways to hide from immune cells and avoid their attack. The recently successful immunotherapy approaches aim to remedy this by taking the brakes off the immune system with the use of targeted drugs, known as immune checkpoint inhibitors.

Whereas adoptive cell immunotherapy also boosts the body's immune defenses against cancer, it does so in a completely different way—by genetically re-engineering a patient's own immune T cells. In the late 1980s, an immunologist was the first to experiment with genetically reprogramming T cells, now known as CAR T cells.

CAR T cells are custom made to work against the cancer in each individual patient. To create these cells, researchers collect immune T cells from the patient and insert an artificial gene into the cells. The gene is designed to endow T cells with chimeric antigen receptors that can detect unique molecules on cancer cells after CAR T cells are multiplied in the laboratory and injected back into the patient. In essence, CAR T-cell therapy is both a gene therapy and an immunotherapy.

When the CAR T-cell receptor attaches to a molecule on a cancer cell, it sends a signal to turn on the destruction machinery of the T cell. Unlike traditional cancer treatments, this living therapy needs to be given to the patient only once, because CAR T cells continue to multiply in the patient's body. As a result, the anticancer effects of CAR T cells can persist and even increase over time.

## ***CAR T-Cell Therapy Is Poised to Transform Childhood ALL Treatment***

In 2017, researchers demonstrated that a CAR T-cell therapy known as tisagenlecleucel can eradicate relapsed ALL in children. This represents one of the most remarkable advances in the treatment of childhood cancer in the last decade and could dramatically change treatment paradigms for this disease. Tisagenlecleucel targets a protein, known as CD19, on malignant and normal B cells.

In the United States, ALL will recur in approximately 600 children and young adults per year, despite achieving a response to initial therapy. After a relapse, ALL is difficult to treat, and survival is usually measured in weeks to months. Remission rates with current standard therapies in prior clinical trials have been only 20% with chemotherapy and 33% with targeted therapy.<sup>10,11</sup>

In a clinical trial of children and young adults with relapsed or refractory ALL, cancer went into remission within 3 months of receiving tisagenlecleucel in 52 (82%) of 63 patients, and 75% of patients remained relapse free at 6 months.<sup>12,13</sup> On the basis of these findings, the FDA approved tisagenlecleucel for the treatment of children and young adults with B-cell ALL in August 2017.<sup>14</sup>

This global clinical trial confirmed the high efficacy that was demonstrated in prior, single-institution trials; however, the rate of immune-related adverse effects was high with tisagenlecleucel. Nearly 50% of patients experienced severe cytokine release syndrome (CRS), a complication during which CAR T cells produce a storm of inflammatory molecules. CRS can cause prolonged fever, low blood pressure, difficulty breathing, and problems with multiple organs. If severe, CRS may require intensive medical care, such as the use of a ventilator or medications known as pressors to increase blood pressure, and seizure medication. Although CRS can be serious and even life threatening, doctors now have an effective medicine (tocilizumab) with which to curb and, in most cases, fully reverse the symptoms.

In addition, neurologic complications occurred in 15% of patients in the study. A broad range of neurologic problems, including word recall issues, difficulty speaking, reduction of alertness, delirium, hallucinations, seizures, and coma, have been reported in prior clinical trials with CAR T-cell therapies. In most patients, such symptoms resolved on their own within a few days without long-term consequences, but several deaths have occurred, with severe neurologic complications in other CAR T-cell trials. In this ALL trial, there were no deaths related to either CRS or neurologic complications.

The global ALL trial also helped to prove that patient access to this novel treatment could be broadened. It was the first time CAR T cells were produced from patient blood cells in an industrial manufacturing facility and distributed to patients via a global supply chain that included 25 centers in the United States, Canada, Europe, Australia, and Japan. Until then, the production of CAR T cells was limited to few academic laboratories, without the ability to ship the cell product to patients around the world.

## ***CAR T-Cell Therapy Is Effective Against Hard-to-Treat Lymphoma in Adults***

CAR T cells that target CD19 have also been proven to be promising against another hard-to-treat cancer, diffuse large B-cell

lymphoma (DLBCL), which is the most common type of non-Hodgkin lymphoma.

In a multicenter clinical trial of patients with DLBCL that worsened after at least two prior therapies, the cancer responded to tisagenlecleucel in 59% of 51 patients and went into remission in 43% of patients.<sup>15</sup> At 6 months, 79% of patients had not had a recurrence of lymphoma. Severe CRS occurred in 25% of patients, and neurologic complications in 13%.

In a different clinical trial, patients with relapsed or refractory DLBCL, refractory primary mediastinal B-cell lymphoma, or transformed follicular lymphoma, received another CAR T-cell product called axicabtagene ciloleucel that also targets CD19.<sup>16</sup> Among the first 92 patients who were treated, the response rate was 82%, with complete remissions occurring in 54% of patients. At a median follow-up of 8.7 months, 39% of patients were still in complete remission. Severe CRS occurred in 13% of patients; neurologic adverse effects occurred in 28% of patients. In late 2017, the FDA approved axicabtagene ciloleucel to treat adults with DLBCL that has not responded to, or has recurred, after at least two prior therapies.<sup>17</sup>

## ***CAR T-Cell Therapy Sends Multiple Myeloma Into Remission***

The studies described above all included CAR T cells that were targeted to the B-cell biomarker CD19. A different type of CAR T-cell therapy that targets a biomarker known as B-cell maturation antigen seems to be effective against multiple myeloma. Despite recent advances in treatment, multiple myeloma—a cancer of plasma cells that make antibodies to fight infections—remains an incurable disease, with only approximately one half of patients living 5 years after diagnosis.

In an early clinical trial, the cancer responded to B-cell maturation antigen CAR T cells in 33 (94%) of 35 patients, and went into complete remission in 14 patients<sup>18</sup> (updated data presented at the 2017 ASCO Annual Meeting in Chicago, IL). Only two patients experienced severe CRS, and none experienced neurologic complications from CAR T-cell therapy.

## **ADVANCES IN CANCER PREVENTION**

Cancer prevention efforts, including cancer screening, vaccination, tobacco control, healthy eating, and physical activity, remain key to reducing the effect of cancer and improving outcomes across communities worldwide. In fact, researchers estimate that 50% of cancer cases and deaths in the United States could be prevented if people adopted simple healthy lifestyle choices that include avoiding smoking and alcohol, maintaining a healthy weight, and exercising regularly.<sup>19</sup>

The top three causes of cancer-related death in low-resource countries—liver cancer, stomach cancer, and cervical cancer—are largely preventable through screening or vaccination. In higher-resource countries, two leading causes of cancer-related deaths—lung and colorectal cancer—can be lowered through lifestyle changes, such as increased physical activity and avoidance of alcohol, tobacco, and processed meat. The same healthy habits can help prevent dozens of other cancers. Emerging research suggests that

human papillomavirus (HPV) vaccination, mainly used for the prevention of cervical cancer, may also help reduce head and neck cancers by lowering oral HPV infections.<sup>20</sup> Finally, safe sun exposure practices and avoidance of indoor tanning can substantially lower the risk for melanoma.

### Preventive Actions to Lower Cancer Risk

Although most Americans (66%) do not smoke, less than half take other important preventive actions to lower their risk of cancer:

- Use sunblock or limit sun exposure without sunblock (48%)
- Exercise regularly (48%)
- Maintain a healthy body weight (41%)
- Limit alcohol consumption (38%) (ASCO's National Cancer Opinion Survey, 2017).

### Avoidable Cancer Risk Factors: E-Cigarettes May Spur Increases in Smoking

In 2017, two federally funded studies provided the clearest estimates of how e-cigarette use may lead to a future habit of smoking cancer-causing traditional tobacco cigarettes. The first study found that people 14 to 30 years of age who used e-cigarettes were 3.6 times more likely to begin smoking traditional cigarettes than those who never used e-cigarettes (this study was funded, in part, by grants from the NCI, the FDA and the National Institute on Drug Abuse).<sup>21</sup> These findings indicate that e-cigarettes are not merely a substitute for traditional cigarettes, but are also a strong risk factor for future smoking. In fact, experts caution that e-cigarette use may lead to an upsurge in smoking prevalence in the long term.

Another study found that, among US teenagers 12 to 17 years of age, the rate of e-cigarette use is already approaching the rate of tobacco cigarette use; 3.1% smoked e-cigarettes compared with 4.6% who smoked tobacco cigarettes in the last 30 days (this study was funded, in part, by grants from the National Institute on Drug Abuse, NIH, and the FDA).<sup>22</sup> However, among adults, e-cigarette use still lags far behind tobacco cigarette use (6.7% v 22.5%). In addition, among those who used more than one tobacco product, 15% of teenagers and 23% of adults used both e-cigarettes and traditional cigarettes.

There is clear evidence that e-cigarettes, smokeless tobacco, and water pipes may cause serious health problems, including cancer. Because of these potential health risks, the FDA began regulating these products, along with other tobacco products, on August 8, 2016. The US Centers for Disease Control and Prevention calls on the public, including parents, health care providers, and teachers, to discourage e-cigarette use among youth. ASCO's [Cancer.Net](#) provides information on the risks of e-cigarettes and smokeless tobacco.

### Cancer Spending

Almost one half (49%) of Americans believe that the government should spend more money on cancer prevention, and 54% think the government should spend more to help Americans afford cancer screenings and care (ASCO's National Cancer Opinion Survey, 2017).

### Avoidable Cancer Risk Factors: Indoor Tanning

UV radiation exposure from indoor tanning is a cause of malignant melanoma. Characterizing the risk of melanoma associated with use of UV radiation-emitting devices is critical for developing policies that reduce the use of such devices, but much of the evidence on this topic has come from case-control studies. In the past year, a large, prospective study was reported that adds new weight to such policy efforts, finding that the risk for melanoma rose with an increasing number of indoor tanning sessions.<sup>23</sup> Compared with those who never used indoor tanning, women who started indoor tanning before 30 years of age had a 30% higher risk for melanoma, which suggests that the harmful effects of indoor tanning are greater at a younger age. For more information on risk factors for melanoma, visit [Cancer.Net](#).

### ASCO Issues Statement on Alcohol as It Relates to Cancer Prevention

In 2017, ASCO issued a statement on alcohol and cancer aimed at drawing attention to alcohol consumption as a contributing factor to the overall cancer burden.<sup>24</sup> ASCO cites between 5% and 6% of new cancer cases and deaths globally as being directly attributable to alcohol. This is particularly concerning as 70% of Americans do not recognize drinking alcohol as a risk factor for cancer, according to the National Cancer Opinion Survey, conducted by ASCO in 2017.

Because drinking alcoholic beverages is a potentially modifiable risk factor for cancer, it can be targeted with preventive interventions at both the policy and individual levels to reduce the incidence of cancer. The evidence-based policy recommendations to reduce excessive alcohol consumption listed in the statement, which was published in *Journal of Clinical Oncology*, are:

- Provide alcohol screening and brief interventions in clinical settings;
- Lower the number of alcohol retailers per capita;
- Increase alcohol taxes and prices;
- Maintain limits on days and hours of sale;
- Enhance enforcement of laws that prohibit sales to minors;
- Restrict youth exposure to advertising of alcoholic beverages;
- Resist additional privatization of retail alcohol sales in communities with current government control;
- Include alcohol control strategies in comprehensive cancer control plans; and
- Support efforts to eliminate the use of "pinkwashing" to market alcoholic beverages (ie, discourage alcoholic beverage companies from exploiting the color pink or pink ribbons to show a commitment to finding a cure for breast cancer) given

the evidence that alcohol consumption is linked to an increased risk of breast cancer.

In addition, not only does excessive alcohol consumption cause cancer, it also can delay or negatively affect cancer treatment. Oncologists are uniquely positioned to identify strategies to help their patients reduce alcohol use; address racial, ethnic, gender, and sexual orientation disparities that may place these populations at increased risk of cancer; and serve as community advisors and leaders to raise awareness of alcohol as a cancer risk behavior.

The link between alcohol use and cancer treatment is one of the most-needed areas for future research in the oncology community, particularly in studying the effect of alcohol consumption while undergoing cancer treatment, including chemotherapy, radiation, and surgery. Other underexplored research areas include the effect of alcohol consumption on postoperative morbidity and targeted therapies, such as immunotherapy and radiation. By increasing the community's knowledge of the ways in which alcohol affects cancer and cancer treatments, oncologists and researchers may have a better understanding of its role in disease progression and therapeutic responsiveness and toxicity.

#### ADVANCES IN CANCER TREATMENT

This year, > 14 million people worldwide will learn they have cancer. According to the latest global statistics, nearly 9 million people a year lose their lives to cancer. That equates to approximately 22,000 cancer deaths per day.<sup>25</sup> The global cancer burden is expected to grow in the future, reaching 21 million patients with cancer and 13 million deaths per year by 2030, as the world's population expands and ages. These sobering statistics underscore the urgency of finding better treatments for patients today and in the future.

The number of new FDA approvals in oncology in recent months is reflective of the scientific fervor and innovation underway to fill this need. From November 2016 through October 2017, the FDA approved a record 18 new cancer therapies and 13 new uses of cancer therapies (Table 1). By comparison, in the same timeframe in the previous year, there were eight new cancer therapies and 13 new uses approved, and a similar number in 2015. Most, if not all, of these new and expanded uses are associated with an improvement in patient survival and/or quality of life.

Also historic, 2017 marked the first approval of a tumor-agnostic therapy and the first adoptive T-cell and gene therapy for cancer, demonstrating that the breakthrough therapy designation and other new approaches in oncology drug development have allowed for a more efficient review and approval process. Research results on other immunotherapies and targeted therapies released in 2017 have changed the treatment paradigms for lung, prostate, and bladder cancer.

#### ***Emergence of Tissue-Agnostic Therapies: Treating Patients on the Basis of the Tumor's Genetics, Rather Than Its Location***

Historically, cancer therapies have been approved for use on the basis of the tumor's location in the body and stage of cancer.

Last year marked a milestone in the history of precision cancer medicine and cancer drug approvals: In May, the FDA approved the first tissue-agnostic treatment, which means that it was approved for use solely on the basis of the genetic make-up of a person's cancer, rather than the type of cancer or its location in the body.<sup>26</sup> Pembrolizumab was approved for the treatment of adults or children with advanced solid tumors that harbor specific genomic changes—mismatch repair (MMR) deficiency or high microsatellite instability (MSI-H).

FDA approval was based on findings from 149 patients with MMR-deficient or MSI-H solid tumors—90 had colorectal cancer and 59 had one of 14 other types of cancer—who were enrolled in five clinical trials. Tumors shrank in 40% of patients, and in 78% of those patients, tumor response lasted  $\geq 6$  months. In one of the studies that included patients with 12 different types of cancer, 21% of patients experienced a complete remission of cancer (this study was funded, in part, by grants from the NIH).<sup>27</sup>

Cells with MMR deficiency have a lower ability to repair damage to their genetic material or DNA and, as a result, accumulate a high number of mutations and make many abnormal proteins. Recent research has shown that programmed death-1/programmed death ligand-1 immune checkpoint inhibitors, which work by unleashing the immune response to cancer, are particularly effective against tumors with MMR deficiency. The reason for this is thought to be a stronger immune response to tumors with more abnormal proteins that the immune system recognizes as foreign.

With this approval, subsets of patients with various types of cancer that are otherwise resistant to treatment gained a highly effective treatment option for controlling the disease, potentially long term. Testing for MMR deficiency or MSI-H will become part of routine diagnostic workup for many patients with solid tumors.

In 2017, researchers presented the early findings from a study of another treatment that seems to work well across many different types of adult and pediatric cancers. The treatment, called larotrectinib, selectively targets a rare genomic abnormality, the tropomyosin receptor kinase (*TRK*) gene fusion.

It is estimated that this abnormality occurs in approximately 0.5% to 1% of many common cancers. In addition, > 90% of certain rare cancers, such as salivary gland cancer, pediatric breast cancer, and infantile fibrosarcoma, have *TRK* fusions.

Of the first 50 adults and children with 17 different cancer types who received larotrectinib in clinical trials, treatment response rate was nearly 80%.<sup>28</sup> Responses to larotrectinib have been long lasting, with 79% ongoing at 12 months after starting treatment. The most common adverse effects were fatigue and mild dizziness, which were expected, as the normal *TRK* protein has a role in controlling balance. No patients needed to stop treatment as a result of adverse effects.

In another clinical trial that enrolled 12 young children with different cancers that harbored *TRK* fusions (infantile fibrosarcoma, other sarcomas, and papillary thyroid cancer) the response rate to larotrectinib was 92%, and responses were also durable. At 6 months, the cancer had worsened in only one patient.<sup>29</sup>

These trials that show strong tumor responses in tumors with *TRK* fusions, regardless of histology, represent a major development in the field. These findings pave the way for a new class of

**Table 1.** FDA Approvals of Cancer Therapies From November 1, 2016, to October 31, 2017

Drug	Indication	Approval Date
<b>New approval</b>		
Rucaparib (Rubraca; Clovis Oncology, Boulder, CO)	For treatment of patients with deleterious BRCA mutation (germline and/or somatic)-associated advanced ovarian cancer who have been treated with two or more chemotherapies.	December 2016
Avelumab (Bavencio; EMD Serono, Darmstadt, Germany)	For the treatment of patients $\geq 12$ years of age with metastatic Merkel cell carcinoma. Avelumab is a PD-L1-blocking human immunoglobulin G1 $\lambda$ monoclonal antibody. This is the first FDA-approved product to treat this type of cancer.	March 2017
Niraparib (Zejula; Tesaro, Waltham, MA)	Maintenance treatment for adult patients with recurrent epithelial ovarian, fallopian tube, or primary peritoneal cancer who are in complete or partial response to platinum-based chemotherapy.	March 2017
Ribociclib (Kisqali; Novartis, Basel, Switzerland)	In combination with an aromatase inhibitor as initial endocrine-based therapy for the treatment of postmenopausal women with HR-positive, HER2-negative advanced or metastatic breast cancer.	March 2017
Brigatinib (Alunbrig; Takeda, Osaka, Japan)	For treatment of patients with metastatic anaplastic lymphoma kinase-positive NSCLC who experienced disease progression on or who are intolerant to crizotinib.	April 2017
Midostaurin (Rydapt; Novartis)	For treatment of adult patients with newly diagnosed AML who are FLT3 mutation-positive, as detected by an FDA-approved test, in combination with standard cytarabine and daunorubicin induction and cytarabine consolidation.	April 2017
Durvalumab (Imfinzi; AstraZeneca, London, United Kingdom)	For treatment of patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or who experience disease progression within 12 months of neoadjuvant or adjuvant treatment with platinum-containing chemotherapy.	May 2017
Rituximab and hyaluronidase human (Rituxan Hycela; Genentech, South San Francisco, CA)	For adult patients with follicular lymphoma, diffuse large B-cell lymphoma, and chronic lymphocytic leukemia.	June 2017
Neratinib (Nerlynx; Puma Biotechnology, Los Angeles, CA)	For extended adjuvant treatment of adult patients with early-stage HER2-overexpressed/amplified breast cancer, to follow adjuvant trastuzumab-based therapy.	July 2017
Daunorubicin and cytarabine (Vyxeos; Jazz Pharmaceuticals, Palo Alto, CA)	For treatment of adults with newly diagnosed therapy-related AML or AML with myelodysplasia-related changes, two types of AML that have a poor prognosis.	August 2017
Enasidenib (Idhifa; Celgene, San Francisco, CA)	For treatment of adult patients with relapsed or refractory AML with an isocitrate dehydrogenase-2 mutation as detected by an FDA-approved test.	August 2017
Inotuzumab ozogamicin (Besponsa; Wyeth, Madison, NJ)	For treatment of adults with relapsed or refractory B-cell precursor ALL.	August 2017
Tisagenlecleucel (Kymriah; Novartis)	For treatment of patients $\leq 25$ years of age with B-cell precursor ALL that is refractory or in second or later relapse.	August 2017
Abemaciclib (Verzenio; Eli Lilly, Indianapolis, IN)	In combination with fulvestrant for women with HR-positive, HER2-negative advanced or metastatic breast cancer with disease progression after endocrine therapy.	September 2017
Bevacizumab-awwb (Mvasi; Amgen, South San Francisco, CA)	Approved as a biosimilar to bevacizumab (Avastin), bevacizumab-awwb is the first biosimilar approved in the United States for the treatment of cancer.	September 2017
Copanlisib (Aliqopa; Bayer HealthCare, Berlin, Germany)	For treatment of adult patients with relapsed follicular lymphoma who have received at least two prior systemic therapies.	September 2017
Gemtuzumab ozogamicin (Mylotarg; Pfizer, New York, NY)	Newly diagnosed CD33-positive AML in adults and for treatment of relapsed or refractory CD33-positive AML in adults and pediatric patients $\geq 2$ years of age. May be used in combination with daunorubicin and cytarabine for adults with newly diagnosed AML or as a stand-alone treatment of certain adult and pediatric patients.	September 2017
Axicabtagene ciloleucel (Yescarta; Kite Pharma, Los Angeles, CA)	For treatment of adult patients with relapsed or refractory large B-cell lymphoma after two or more lines of systemic therapy.	October 2017
<b>New use</b>		
Daratumumab (Darzalex; Janssen, Beerse, Belgium)	In combination with lenalidomide and dexamethasone, or bortezomib and dexamethasone, for the treatment of patients with multiple myeloma who have received at least one prior therapy.	November 2016
Nivolumab (Opdivo; Bristol-Meyers Squibb, New York, NY)	Recurrent or metastatic squamous cell carcinoma of the head and neck with disease progression on or after a platinum-based therapy.	November 2016
Lenalidomide (Revlimid; Celgene)	Maintenance therapy for patients with multiple myeloma after autologous stem-cell transplantation.	February 2017
Nivolumab (Opdivo)	For treatment of patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or experience disease progression within 12 months of neoadjuvant or adjuvant treatment with a platinum-containing chemotherapy.	February 2017
Osimertinib (Tagrisso; AstraZeneca)	For treatment of patients with metastatic EGFR T790M mutation-positive NSCLC, as detected by an FDA-approved test, who experienced disease progression on or after EGFR tyrosine kinase inhibitor therapy.	March 2017

(continued on following page)

**Table 1.** FDA Approvals of Cancer Therapies From November 1, 2016, to October 31, 2017 (continued)

Drug	Indication	Approval Date
Palbociclib (Ibrance; Pfizer)	HR-positive, HER2-negative advanced or metastatic breast cancer in combination with an aromatase inhibitor as initial endocrine-based therapy in postmenopausal women.	March 2017
Pembrolizumab (Keytruda; Merck & Co, Kenilworth, NJ)	For treatment of adult and pediatric patients with refractory classic Hodgkin lymphoma or those who have experienced relapse after three or more prior lines of therapy.	March 2017
Regorafenib (Stivarga; Bayer HealthCare Pharmaceuticals)	For treatment of patients with HCC who have been previously treated with sorafenib.	April 2017
Avelumab (Bavencio)	For patients with locally advanced or metastatic urothelial carcinoma who experienced disease progression during or after platinum-containing chemotherapy or within 12 months of neoadjuvant or adjuvant platinum-containing chemotherapy.	May 2017
Pembrolizumab (Keytruda)	In combination with pemetrexed and carboplatin for treatment of patients with previously untreated metastatic nonsquamous NSCLC.	May 2017
Pembrolizumab (Keytruda)	For patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or within 12 months of neoadjuvant or adjuvant treatment with platinum-containing chemotherapy.	May 2017
Nivolumab (Opdivo)	For treatment of HCC in patients who have been previously treated with sorafenib.	September 2017
Pembrolizumab (Keytruda)	For patients with recurrent locally advanced or metastatic, gastric, or gastroesophageal junction adenocarcinoma whose tumors express PD-L1 as determined by an FDA-approved test.	September 2017

Abbreviations: ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; EGFR, epidermal growth factor receptor; FDA, US Food and Drug Administration; HCC, hepatocellular carcinoma; HER2, human epidermal growth factor receptor 2; HR, hormone receptor; NSCLC, non-small-cell lung cancer; PD-L1, programmed death-ligand 1.

drugs for rare tumors and define a new era in oncology. Equally important, they set a new milestone in precision medicine for pediatric oncology, for which it is just starting to be applied.

### A Policy Focus: FDA's New Plan to Increase Medical Innovation

The FDA has launched a new Medical Innovation Development Plan designed to facilitate the development of innovative drugs by updating FDA's regulatory tools and policies. FDA intends to use the new plan to streamline the path to market for targeted therapies and other novel drugs to encourage innovation in therapies. In particular, the plan will focus on facilitating the approval of tumor-agnostic therapies—medicines that work comparatively well in many different types of cancer. As part of the plan, FDA will develop guidance on strategies to improve the efficiency of clinical trials, including adaptive trial designs.

### New Treatments Slow Advanced Lung Cancer Growth

Lung cancer is among the most common types of cancer and the leading cause of cancer death in men and women worldwide. Last year, an estimated 156,000 people died of this disease in the United States.<sup>30</sup>

The good news is that these grim statistics have been steadily improving. After decades of increases, rates of lung cancer deaths began to decline in the early 1990s and have been falling, on average, 2.5% each year between 2005 and 2014. The 5-year

survival rate increased from only 11% in 1975 to 18% in the most recent time period measured (2007 to 2013).<sup>30</sup> For more information about lung cancer, visit [Cancer.Net](#).

This progress is directly tied to changes in therapy that have occurred during the past two decades, with the development of new therapies that not only work better, but that often also have fewer adverse effects than standard chemotherapy, radiation, and surgery.

In 2017, two new regimens were introduced for the initial treatment of the most advanced form of non-small-cell lung cancer (NSCLC)—a targeted medicine, alectinib, and an immune checkpoint inhibitor, pembrolizumab, combined with chemotherapy. For patients with earlier-stage disease, a clinical trial demonstrated that administering a new immune checkpoint inhibitor, durvalumab, after standard chemotherapy and radiation dramatically slowed cancer growth.

*New targeted medicine works better than chemotherapy and with fewer adverse effects.* Up to 7% of NSCLCs have a genetic change known as anaplastic lymphoma kinase (ALK) rearrangement that results in an abnormal ALK protein that causes cells to grow and spread. The first medicine that targets ALK, crizotinib, was approved by the FDA in 2011, and more potent medicines have been introduced since that time. In 2017, two clinical trials showed that one new ALK medicine, alectinib, is more effective than crizotinib for patients with previously untreated NSCLC, and also causes fewer adverse effects.<sup>32,33</sup> In the larger of the two trials, during a median follow-up of 18 months, 41% of patients who received alectinib had their cancer worsen, or died, compared with 68% of those who received crizotinib.<sup>33</sup> Alectinib was also better at curbing the growth of cancer that had spread to the brain; only 12% of patients had worsening brain metastases compared with 45% of those who received crizotinib.

## Changing Paradigms in Lung Cancer Treatment

The first paradigm shift occurred in the mid-1990s with research that demonstrated that giving chemotherapy after surgery, known as adjuvant therapy, helps patients live longer, and that combining chemotherapy with radiation therapy can additionally improve the outlook for some patients with lung cancer. Several new chemotherapies were introduced, such as paclitaxel, docetaxel, gemcitabine, and pemetrexed.

The second paradigm shift in the treatment of advanced lung cancer occurred in 2004, when scientists discovered the association between certain mutations in the epidermal growth factor receptor (EGFR) and response to EGFR-targeted drugs, such as gefitinib. EGFR is a protein that helps cancer cells grow and is mutated in 25% of lung cancers. In the ensuing years, several EGFR-targeted drugs were developed (erlotinib, afatinib, and osimertinib) as well as treatments that target less common genetic alterations (*BRAF* gene mutations [dabrafenib plus trametinib] and *ALK* gene rearrangements [crizotinib, ceritinib, and alectinib]).

Finally, the introduction of immunotherapy in 2015 marks the third paradigm shift in the treatment of lung cancer. Immune checkpoint inhibitors, pembrolizumab and nivolumab, were first approved for the treatment of advanced NSCLC that worsens during or after standard chemotherapy, and atezolizumab was approved in 2016. That same year, the FDA approved the first use of immunotherapy for previously untreated advanced NSCLC, pembrolizumab. Currently, immunotherapy is also being studied in earlier stages of disease. In a clinical trial of patients with locally advanced, stage III NSCLC, the checkpoint inhibitor durvalumab delayed disease worsening by nearly 1 year. The ongoing ALCHEMIST immunotherapy trial ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02595944) identifier: NCT02595944) explores whether giving nivolumab after standard treatment of early-stage lung cancer can reduce recurrences and help patients live longer.

Reflecting on these developments, ASCO's clinical practice guideline for advanced NSCLC was revised in 2017 to add immunotherapy as a standard treatment approach for either first-line or second-line settings.<sup>31</sup>

*Role of immunotherapy continues to expand, slowing advanced cancer growth.* In 2017, the FDA granted accelerated approval to pembrolizumab combined with standard chemotherapy (carboplatin and pemetrexed) as an initial treatment of metastatic NSCLC.<sup>34</sup> The approval was based on an early clinical trial that found that the chance of cancer worsening was cut nearly in half by adding pembrolizumab to chemotherapy. The median time until cancer worsening was 13 months with pembrolizumab and chemotherapy versus 9 months with chemotherapy alone; however, the incidence of serious treatment-related adverse effects was

higher with combined modality treatment (41%) than chemotherapy alone (28%). An international phase III clinical trial is underway to confirm these findings ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02578680) identifier: NCT02578680).

A newer immune checkpoint inhibitor, durvalumab, also seems to have a role in lung cancer treatment. These findings mark the first advance in years for the treatment of stage III, locally advanced NSCLC. This type of cancer accounts for approximately one third of all NSCLCs. The standard treatment of patients with tumors that cannot be surgically removed is chemotherapy with radiation, or chemoradiotherapy. Despite this treatment, cancer quickly worsens, and only 15% of patients are alive 5 years after diagnosis.

In this trial, patients whose cancer did not worsen after chemoradiotherapy were randomly assigned to receive durvalumab or placebo.<sup>35</sup> The median time until cancer worsening was 16.8 months with durvalumab and 5.6 months with placebo, and the median time until patients died or the cancer spread to distant parts of the body was 23.2 months versus 14.6 months, respectively.

## Continued Research on Immune Checkpoint Inhibitors

Uses for immune checkpoint inhibitors—treatments that help unleash the body's immune response to cancer—continue to expand to more cancer types, which has affirmed the role of this strategy, and particularly agents that target the programmed death-1/programmed death ligand-1 checkpoint in cancer treatment. Key recent studies in this area are listed in [Table 2](#).

## Immunotherapy Changes the Treatment Paradigm for Bladder Cancer

Bladder cancer is another type of cancer for which immunotherapy has transformed the outlook for patients. The most common type of bladder cancer, urothelial cancer, is difficult to treat at advanced stages. With standard chemotherapy, only 5% of patients are alive 5 years after diagnosis. For more information about bladder cancer, visit [Cancer.Net](https://www.cancer.net).

After 30 years of limited progress, the outlook for these patients is now improving with the arrival of a series of immunotherapies ([Table 3](#)). For some patients, immunotherapy has opened a treatment option where none previously existed. For others, it offers a chance to live longer with fewer treatment-related adverse effects.

In May 2016, atezolizumab became the first immune checkpoint inhibitor to receive FDA approval for the treatment of advanced bladder cancer.<sup>49</sup> In 2017, the FDA approved four other immune checkpoint inhibitors for patients with previously treated urothelial cancer that worsened, despite platinum-based chemotherapy—nivolumab, avelumab, pembrolizumab, and durvalumab.<sup>50-53</sup> In a large clinical trial that led to the approval of pembrolizumab, patients who received the immunotherapy lived approximately 3 months longer than those who received chemotherapy. Meanwhile, the rate of serious treatment-related adverse effects was more than three times lower in the pembrolizumab group than in the chemotherapy group (15% v 49%).<sup>54</sup>

Recent clinical trials also point to the potential use of immunotherapy as an initial treatment for advanced bladder cancer. As a result of physical frailty and certain health conditions, up to two thirds of patients are not eligible for cisplatin-based chemotherapy,

**Table 2.** Notable Recent Advances With Immune Checkpoint Inhibitors

Cancer Type	Key Finding	First Author
Breast cancer	Addition of pembrolizumab to standard neoadjuvant therapy for high-risk, HER2-negative breast cancer increased rates of pathologic complete response, especially in women with triple-negative breast cancer—a 50% higher rate.	Nanda <sup>36</sup>
Head and neck cancer	Patients with recurrent or metastatic squamous cell head and neck cancer who received nivolumab lived a median of 2-3 months longer than did those who received standard therapy of investigator's choice.	Gillison <sup>37</sup>
Head and neck cancer	Compared with patients with recurrent or metastatic squamous cell head and neck cancer who received standard therapy of investigator's choice, those who received nivolumab had fewer symptoms and better quality of life for 15 weeks.	Harrington <sup>38</sup>
Kidney cancer	Response rate was higher in patients with advanced kidney cancer who received nivolumab as initial treatment than in those who received standard sunitinib (42% v 26%, respectively), and time until cancer worsening was longer (median, 11.6 months v 8.4 months, respectively).	Escudier <sup>39</sup>
Liver cancer	In an early clinical trial of patients with advanced liver cancer, response rate to nivolumab was 20%, and adverse effects were manageable.	El-Khoueiry <sup>40</sup>
Lung cancer	In a clinical trial of patients with advanced small-cell lung cancer, 1-year survival rate was 30% for those who received nivolumab and 42% for those who received nivolumab with ipilimumab.	Hellmann <sup>41</sup>
Lung cancer	Treatment with checkpoint inhibitor durvalumab after standard chemotherapy and radiation delayed worsening of stage III NSCLC by 11 months.	Antonia <sup>42</sup>
Skin cancer	Compared with patients with advanced melanoma who received adjuvant ipilimumab, those who received nivolumab had a higher rate of recurrence-free survival at 12 months (70% v 61%, respectively) and a lower rate of severe adverse effects (14% v 46%, respectively).	Weber <sup>43</sup>
Skin cancer	In patients with advanced melanoma, 3-year survival rate was higher with nivolumab and ipilimumab combined (55%) than with either nivolumab alone (52%) or ipilimumab alone (32%).	Wolchok <sup>44</sup>
Skin cancer	In a clinical trial of patients with advanced Merkel cell carcinoma, response rate to PD-L1 inhibitor avelumab was 32% during a median follow-up of 10 months.	Kaufman <sup>45</sup>
Skin cancer	An early clinical trial suggests that a new PD-1 inhibitor, REGN2810, may be effective against a common skin cancer, cutaneous squamous cell carcinoma. Response rate in patients with advanced disease was 52%.	Papadopoulos <sup>46</sup>
Stomach cancer	A large clinical trial shows that nivolumab is effective as a salvage therapy for people with advanced gastric or gastroesophageal junction cancer that worsens despite chemotherapy. At 12 months, 27% of patients were alive compared with 11% of those who received placebo.	Kang <sup>47</sup>
Stomach cancer	Pembrolizumab showed promising efficacy in a clinical trial of patients with previously treated, advanced stomach or gastroesophageal junction cancer. Response rate was 11%, and 12-month survival rate was 23%.	Fuchs <sup>48</sup>

Abbreviations: HER2, human epidermal growth factor receptor 2; NSCLC, non-small-cell lung cancer; PD-L1, programmed death-ligand 1.

which is the standard initial treatment of this disease. Alternative chemotherapies exist, but are less effective; therefore, many such patients receive only supportive care.

In 2017, the FDA granted accelerated approval to pembrolizumab for this indication.<sup>53</sup> The approval was based on a clinical trial of patients with locally advanced or metastatic urothelial cancer who were not eligible for cisplatin-containing

chemotherapy.<sup>55</sup> At a median follow-up of 8 months, treatment response rate was 28%, and responses lasted up to 18 months (median duration not reached). Pembrolizumab was well tolerated, with serious adverse effects occurring in 18% of those treated.

In another clinical trial, atezolizumab also was proven to be effective as an initial therapy for patients with advanced urothelial cancer who cannot receive cisplatin-containing chemotherapy.<sup>56</sup>

**Table 3.** Recent US Food and Drug Administration Approvals of Immunotherapies for Bladder Cancer

Drug Name (trade name)	Indication	Date Approved
Atezolizumab (Tecentriq; Genentech Oncology, South San Francisco, CA)	For treatment of patients with locally advanced or metastatic urothelial carcinoma who experience progression during or after platinum-containing chemotherapy or within 12 months of treatment with platinum-containing chemotherapy.	May 2016
Nivolumab (Opdivo; Bristol-Myers Squibb, Sunnyvale, CA)	For treatment of patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or who experience disease progression within 12 months of neoadjuvant or adjuvant treatment with a platinum-containing chemotherapy.	February 2017
Avelumab (Bavencio; EMD Serono, Darmstadt, Germany)	For patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or within 12 months of neoadjuvant or adjuvant platinum-containing chemotherapy.	May 2017
Durvalumab (Imfinzi; AstraZeneca, London, United Kingdom)	For treatment of patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or who experience disease progression within 12 months of neoadjuvant or adjuvant treatment with platinum-containing chemotherapy.	May 2017
Pembrolizumab (Keytruda; Merck & Co, Kenilworth, NJ)	For patients with locally advanced or metastatic urothelial carcinoma who experience disease progression during or after platinum-containing chemotherapy or within 12 months of neoadjuvant or adjuvant treatment with platinum-containing chemotherapy.	May 2017

At a median follow-up of 18 months, the treatment response rate was 23% and median survival was nearly 16 months. These advances have defined new standards of care for patients with advanced bladder cancer.

### A Policy Focus: Promoting Patient Participation in Clinical Trials

Clinical trials are critical for the advancement of new cancer treatments, but only a small percentage of patients (< 3%) in the United States participate in clinical trials.<sup>57</sup> In clinical trials, eligibility criteria define the trial population and protect the safety of trial participants, particularly those who may be more vulnerable to the adverse effects of treatment in a clinical trial; however, overly restrictive eligibility criteria can make trial findings more difficult to apply to the treatment of real-world patients with cancer.

ASCO, in collaboration with the nonprofit advocacy organization, Friends of Cancer Research, issued a joint research statement calling for the use of more inclusive eligibility criteria for cancer clinical trials. The statement, published in *Journal of Clinical Oncology*, provides recommendations to address eligibility criteria in five areas: minimum age requirements for trial enrollment, patients with HIV/AIDS, patients with brain metastases, patients experiencing organ dysfunction, and patients with prior and concurrent malignancies.

ASCO is working with the FDA and clinical trial sponsors to identify additional opportunities to safely expand eligibility criteria for oncology trials.

### New Approaches Help People With Brain Cancer Live Longer

*Two new regimens extend survival in patients with glioblastoma.* Grade IV glioma, or glioblastoma (GBM), is one of the most common and deadliest types of brain cancer in adults. With current therapies, fewer than one in 10 patients live 5 years after a diagnosis of GBM. There are now two new strategies that can possibly lengthen life for people with GBM. For more information about GBM and other brain tumors, visit [Cancer.Net](http://Cancer.Net).

The first involves a novel technology known as tumor-treating fields (TTFs). These are low-intensity electrical fields that are thought to slow cancer growth by blocking cell division. TTFs are delivered to the brain tumor through the skin from a device that patients wear on their head continuously at least 18 hours a day. Preliminary findings from a clinical trial of TTFs led to the FDA approval of the device in 2015 for use in combination with temozolomide chemotherapy, after surgery, chemotherapy, and radiation, for patients with newly diagnosed GBM.<sup>58</sup>

In 2017, researchers reported longer follow-up findings from the same clinical trial.<sup>59</sup> The risk of death was reduced by 37% for patients who used the device compared with those who received chemotherapy alone, with a median survival of 21 months with TTFs and chemotherapy, versus 16 months with chemotherapy

alone. The addition of TTFs also doubled the 5-year survival rate, from 5% to 13%.

The second advance is the discovery that adding temozolomide chemotherapy to short-course radiotherapy results in longer survival than radiotherapy alone in elderly patients with GBM.<sup>60</sup> The prognosis for elderly patients with GBM is poor and questions remain about the optimal treatment of older patients.

In the study, patients who received temozolomide with radiotherapy had a 33% lower risk of death and lived longer than those who received radiotherapy alone (median, 9.3 months *v* 7.6 months, respectively), whereas quality of life was similar between the two groups. Researchers also confirmed prior findings that suggested that a genomic biomarker, methylation of the O6-methylguanine–DNA methyltransferase (*MGMT*) gene, predicts better outcomes in patients with GBM. Among patients with methylated *MGMT*, median survival with radiotherapy plus temozolomide was 13.5 months compared with 7.7 months with radiotherapy alone.

*Adding chemotherapy to radiation slows glioma growth.* Grade III glioma, or anaplastic glioma, commonly occurs in young adults. This type of brain tumor can grow quickly and can recur as GBM despite treatment.

For patients with anaplastic glioma with a genomic abnormality known as 1p19q codeletion (loss of chromosome arms 1p and 19q) there is clear evidence that adding chemotherapy to radiation therapy improves survival; however, there are conflicting reports of the value of adjuvant (postsurgery) chemotherapy for anaplastic glioma without 1p19q codeletion. Preliminary findings from a large clinical trial have clarified the role of adjuvant temozolomide in this patient population.<sup>61</sup>

The 5-year survival rate was markedly longer when temozolomide was added to radiation therapy (56%) than when patients received radiation therapy alone (44%). Addition of temozolomide after radiation therapy delayed disease worsening by > 2 years (median, 43 months *v* 19 months, respectively). Temozolomide was well tolerated, with serious adverse effects occurring in only 12% of patients. These findings have established this regimen as a new standard of care for patients with anaplastic glioblastoma without 1p19q codeletion.

### New Targeted Therapy Regimens for Breast Cancer

*For BRCA-related breast cancer, olaparib is more effective than chemotherapy.* Findings from a large clinical trial of women with advanced, BRCA-related breast cancer point to a new type of treatment for the disease—poly (ADP-ribose) polymerase (PARP) inhibitors. Compared with standard chemotherapy, the PARP inhibitor olaparib lowered the risk of cancer worsening by 42% and extended the time until the cancer worsened by approximately 3 months.<sup>62</sup> Severe adverse effects were less common with olaparib, occurring in 37% of patients compared with 50% of those who were treated with chemotherapy. For more information about advanced breast cancer, visit [Cancer.Net](http://Cancer.Net).

Whereas several PARP inhibitors are already approved by the FDA for the treatment of ovarian cancer, this is the first study to demonstrate clinical benefit from this approach in patients with breast cancer. Several other large clinical trials of olaparib in breast cancer are underway ([ClinicalTrials.gov](http://ClinicalTrials.gov) identifiers: NCT02032823 and NCT03167619).

Up to 3% of all breast cancers occur in women who carry inherited changes in genes *BRCA1* and *BRCA2*. These changes undermine the ability of the cell to repair damaged DNA. Because of their underlying defect in DNA repair, cancer cells with *BRCA* mutations are particularly vulnerable to treatments that target PARP, another key component of the cell's DNA repair machinery.

*Dual targeted therapy lowers the risk of invasive breast cancer in some women.* A clinical trial of nearly 5,000 women with early, human epidermal growth factor receptor 2 (HER2)-positive breast cancer has suggested that adding a second HER2-targeted medicine, pertuzumab, to the standard regimen of the HER2-blocking therapy trastuzumab and chemotherapy may help some women.<sup>63</sup>

Recurrences were reduced by approximately one fifth in patients who received pertuzumab with trastuzumab after surgery compared with those who received trastuzumab and placebo. At 3 years, an estimated 94.1% of patients in the pertuzumab group were free of invasive breast cancer compared with 93.2% of patients in the placebo group. Addition of pertuzumab did not increase the rate of heart problems, which is the greatest concern with HER2-targeted therapy.

Treatment benefit was particularly evident in patients with breast cancer that had spread to lymph nodes—an estimated 92% were free of invasive cancer compared with 90.2% of those who received placebo at 3 years. In contrast, in patients with node-negative cancer, pertuzumab did not improve invasive disease-free survival.

These findings may set a new standard of care for some patients with node-positive, HER2-positive, hormone receptor-negative breast cancer who have a higher risk of developing invasive breast cancer. Meanwhile, researchers are trying to identify biomarkers that may help predict which groups of patients will benefit most from pertuzumab. The good news from this trial is that patients with HER2-positive breast cancer—the group of patients that used to have the worst prognosis—are doing so well on trastuzumab alone.

### **Research Supports Extended Hormone Therapy for Patients With Higher-Risk Breast Cancer**

To lower the chance of cancer recurrence, many women with early-stage breast cancer receive hormone therapy after surgery. Until recently, the recommended standard duration of such therapy had been 5 years, but new research findings suggest that extending hormone therapy may benefit some patients.

In 2016, a large clinical trial found that, in women with hormone receptor-positive, early breast cancer who received the aromatase inhibitor letrozole for 10 years, breast cancer recurrences or new cancers in the opposite breast were reduced by approximately one third compared with women who received 5 years of aromatase inhibitor therapy.<sup>64</sup> Later that year, an even larger trial reported a similar (29%) reduction in the risk of breast cancer recurrence or cancer in the opposite breast for women who received 5 additional years of letrozole after 5 years of aromatase inhibitor therapy (this study was funded, in part, by a grant from the NCI).<sup>65</sup> However, longer hormone therapy did not improve overall or disease-free survival—the primary end point of the

study—and was accompanied by a small increase in the risk of blood clots.

In late 2017, researchers reported on an improvement in disease-free survival for women who received extended aromatase inhibitor therapy after tamoxifen.<sup>66</sup> In that clinical trial, 5-year disease-free survival was 83% among women who received anastrozole for 6 years, and 79% among those who received it for 3 years; however, patients in the 6-year therapy group had more adverse effects, including joint and muscle pain.

Taken together, these findings support longer hormone therapy for women with early breast cancer who have a higher risk for recurrence on the basis of tumor features and patient-specific factors. Discussion of therapy duration should take into consideration the adverse effects the patient experienced during initial hormone therapy, as well as ongoing health conditions. If patients are carefully selected for extended hormone therapy, breast cancer mortality can be additionally reduced without overtreatment.

### **Bevacizumab May Help Some Women With Ovarian Cancer Live Longer**

Women with recurrent ovarian cancer have a short life expectancy and limited treatment options. In late 2016, the FDA approved a new regimen that improves their outlook—adding bevacizumab to standard platinum-based chemotherapy. This was the first approval of a new treatment of platinum-sensitive ovarian cancer in more than a decade. Bevacizumab had been previously approved for the treatment of women with platinum-resistant ovarian cancer. For more information about ovarian cancer, visit [Cancer.Net](http://Cancer.Net).

This new approval was based on a clinical trial in which women received standard chemotherapy alone or bevacizumab with standard paclitaxel plus carboplatin chemotherapy, followed by maintenance therapy with bevacizumab (this study was funded, in part, by a grant from the NCI).<sup>67</sup> Addition of bevacizumab significantly extended median time until cancer worsening to 13.8 months compared with 10.4 months with chemotherapy alone. Overall survival was also longer with bevacizumab than with chemotherapy alone (median, 42 months *v* 37 months), but this difference was not statistically significant; however, the rate of severe adverse effects was higher in the bevacizumab group (96%) than in the standard therapy group (86%), with high blood pressure and fatigue being the most common adverse effects with bevacizumab.

### **New Maintenance Therapies Keep Recurrent Ovarian Cancer From Worsening**

Maintenance therapy for ovarian cancer is critical because of the high rate of recurrence, despite initial response to standard platinum-based chemotherapy. In 2017, the FDA approved a new maintenance treatment, the PARP inhibitor olaparib, for women with recurrent ovarian cancer who responded to platinum-based chemotherapy.<sup>68</sup> Approval was based on a clinical trial in which olaparib was demonstrated to markedly slow cancer growth.<sup>69</sup> Median time until cancer worsening was 19.1 months with olaparib versus 5.1 months with placebo. The most common severe adverse effects of olaparib were anemia and fatigue.

Meanwhile, in a clinical trial of maintenance therapy with the PARP inhibitor rucaparib, the growth of platinum-sensitive, recurrent ovarian cancer was also slowed.<sup>70</sup> Overall, rucaparib delayed cancer worsening by approximately 5 months longer than placebo (10.8 months *v* 5.4 months, respectively). Benefit was greatest among women with *BRCA* mutations (median time until cancer worsening was 16.6 months with rucaparib *v* 5.4 months with placebo), as well as women with tumors that harbored defects in DNA repair machinery (median time until cancer worsening was 13.6 months with rucaparib *v* 5.4 months with placebo). The most common severe adverse effects of rucaparib were anemia and liver enzyme abnormalities. These findings have been submitted to the FDA for the approval of rucaparib in this setting.

### A Policy Focus: Learning More About Older Adults With Cancer

More than 60% of cancer diagnoses in the United States occur in people age  $\geq 65$  years—a population that will grow rapidly over the coming years. Whereas 70% of cancer deaths occur in older adults, and older adults make up the majority of survivors of cancer, the evidence base for treating this population is sparse. Older adults are under-represented in clinical trials, and trials designed specifically for older adults are rare.

ASCO and the FDA held a workshop in November 2017 to discuss ASCO's recommendations to improve the evidence base for treating older adults. ASCO is continuing to urge federal agencies and the cancer research community to increase the enrollment of older adults in clinical trials and use other strategies to collect evidence on this population of patients.

### Precision Medicine Helps People With Melanoma Live Longer

Whereas early-stage melanoma is curable with surgery, patients with stage III melanoma face a much higher chance of recurrence after surgery, and many ultimately die of metastatic disease. New findings suggest that a precision medicine approach that combines two targeted medicines can improve outcomes for a subset of patients.

The study was conducted in patients with tumors that harbored *BRAF* gene mutations, which occur in approximately 40% of all melanomas. *BRAF* mutations turn on a molecular pathway known as mitogen-activated protein kinase. Prior research has demonstrated that blocking this pathway with two medicines in combination—dabrafenib and trametinib—helps patients with metastatic, *BRAF*-mutated melanoma live longer (the FDA approved this regimen in 2014).

In 2017, researchers reported that the combination of dabrafenib and trametinib can also help patients with stage III melanoma by lowering the risk for recurrence after surgery.<sup>71</sup> Estimated 3-year relapse-free survival rates were 58% with targeted therapy and 39% with placebo. Overall survival rates were 86% with targeted therapy versus 77% with placebo.

Combined targeted treatment was associated with a considerable rate of serious adverse effects (36%), including potentially fatal pneumonia. Overall, 26% of patients had to stop treatment earlier than the planned 12-month duration as a result of adverse effects. Currently, there is insufficient evidence to inform the most beneficial duration of adjuvant therapy for stage III melanoma. For more information about melanoma, visit [Cancer.Net](http://Cancer.Net).

### New Treatment Paradigms Help Men With Prostate Cancer Live Longer

*Adding hormone therapy to radiation boosts the long-term survival rate.* More than 30% of men who receive surgery for localized prostate cancer experience a recurrence of cancer. Patients who experience a local recurrence after surgery receive radiation therapy, but despite the therapy, the cancer eventually worsens in up to 50% of men. For more information about prostate cancer, visit [Cancer.Net](http://Cancer.Net).

A recent large clinical trial found that adding androgen-deprivation therapy to radiation therapy helps men, who experience a local recurrence after surgery, live longer (this study was funded, in part, by a grant from the NCI).<sup>72</sup> The study enrolled men with prostate-specific antigen levels between 0.2 ng/mL and 4 ng/mL at least 8 weeks after surgery. Men were randomly assigned to receive androgen-deprivation therapy bicalutamide during and 24 months after radiation therapy or radiation therapy and placebo. Survival rate at 12 years was 76% in the bicalutamide group versus 71% in the placebo group. More men in the placebo group developed metastatic prostate cancer (23% *v* 14%, respectively) and more died of the disease (13% *v* 6%, respectively). Late effects of radiotherapy were similar between groups, but gynecomastia (swelling of breast tissue) was much more common with bicalutamide, occurring in 70% of men compared with 11% of those who received placebo.

Whereas other clinical trials are investigating the use of newer hormonal therapies with radiation therapy after prostate cancer surgery ([ClinicalTrials.gov](http://ClinicalTrials.gov) identifiers: NCT00541047 and NCT00423475), these findings provide strong evidence to support the combination of androgen-deprivation therapy with radiation therapy for men who experience a local recurrence after surgery.

*A new standard of care for advanced prostate cancer.* Two large studies presented in 2017 demonstrated that adding abiraterone to standard androgen-deprivation therapy helps men with metastatic prostate cancer live longer. Whereas androgen-deprivation therapy slows prostate cancer growth by preventing the testicles from making testosterone, certain other organs in the body continue making small amounts of testosterone and other androgens. Abiraterone stops the production of both testosterone and other androgens throughout the body by blocking an enzyme that converts other hormones to androgens.

In the first study, patients with high-risk metastatic prostate cancer were randomly assigned to receive androgen-deprivation therapy with either abiraterone or placebo.<sup>73</sup> At a median follow-up of 30 months, men who received abiraterone had a 38% lower risk of death than did those who received placebo. Abiraterone also more than doubled the median time until cancer worsening from 15 months to 33 months.

The second study, which included men with high-risk, locally advanced or metastatic prostate cancer, found that patients who received abiraterone with standard androgen-deprivation therapy had a 37% lower risk of death than those who received androgen-deprivation therapy alone.<sup>74</sup> The 3-year survival rate was 76% with standard therapy alone and 83% with standard therapy plus abiraterone.

Taken together, these findings define a new standard of care for men with metastatic prostate cancer.

### **Research Informs Decision Making for Early Prostate Cancer Treatment**

Men with early (localized) prostate cancer can choose one of three standard treatments, which include surgery, radiation therapy, or active surveillance. A recent clinical trial found no significant differences in 10-year survival with any approach, although active surveillance was associated with a higher risk of cancer worsening and metastasis.<sup>75</sup>

A subsequent analysis of patient-reported outcome data from the same clinical trial showed that adverse effects differed among the three approaches.<sup>76</sup> Surgery had a greater negative impact on sexual function and urinary continence than either radiation therapy or active surveillance. In the active surveillance group, sexual and urinary function declined gradually. Bowel function problems were worse in the radiotherapy group than in the other two groups at 6 months, but subsequently recovered somewhat. There were no significant differences among the treatment groups in anxiety, depression, or general health-related or cancer-related quality of life.

Another clinical trial that compared surgery with active surveillance found that men who received surgery had more sexual dysfunction and urinary incontinence through 10 years than did those who received active surveillance (this study was funded, in part, by grants from the US Department of Veterans Affairs, the Agency for Healthcare Quality and Research, and the NCI).<sup>77</sup> Limitations in activities of daily living through 2 years were also greater in the surgery group.

In addition, two large, population-based studies that observed men with localized prostate cancer for 3 years also found that patterns of adverse effects differed depending on the type of treatment men received.<sup>78,79</sup>

Taken together, these findings from clinical trial participants as well as real-world patients will help clinicians better counsel patients about the risks and benefits of various treatments for localized prostate cancer.

### **Less Is More: Preserving Quality of Life With Less Treatment**

*Shorter chemotherapy for colon cancer is safe and lowers the chance of nerve damage.* For patients with stage III colon cancer, administering chemotherapy after surgery (adjuvant chemotherapy) lowers the chance that the cancer will come back. The standard 6-month course of adjuvant oxaliplatin-based chemotherapy can cause peripheral neuropathy. Symptoms of this condition, which include pain, tingling, numbness, and muscle weakness, sometimes persist indefinitely. Longer chemotherapy also typically means more diarrhea and fatigue, more doctor

appointments, blood draws, and time away from work and social gatherings.

Six clinical trials with 12,800 patients in North America, Europe, and Japan explored whether adjuvant chemotherapy regimens that consisted of either FOLFOX (infusional fluorouracil, leucovorin, and oxaliplatin) or CAPOX (capecitabine and oxaliplatin) could be shortened to 3 months without compromising survival. In 2017, researchers reported on the analysis of pooled data from the trials (this study was funded, in part, by a grant from the NCI).<sup>80</sup>

The chance of being free from colon cancer at 3 years was only slightly lower with 3 months of chemotherapy than with 6 months (74.6% v 75.5%, respectively). For patients with a lower risk of cancer recurrence (T1 to T3 N1 colon cancer), the chance of being cancer free at 3 years was nearly identical between the two groups—83.1% in those who received a 3-month course and 83.3% in patients who received a 6-month course.

The rate of clinically meaningful nerve damage differed depending on the type of chemotherapy regimen received, but was consistently lower for people who received 3 months versus 6 months of chemotherapy (15% v 45% with FOLFOX and 17% v 48% with CAPOX, respectively).

These findings, relevant to approximately 400,000 patients with stage III colon cancer worldwide, should inform conversations between oncologists and their patients. For patients with lower-risk stage III colon cancer, the shorter 3-month course will likely become the new standard of care. For patients with higher-risk cancer, decisions on shorter-duration therapy will have to be carefully weighed against the risks of recurrence, patient ability to tolerate chemotherapy, and patient preferences. For more information about colon cancer, visit [Cancer.Net](#).

*Less extensive surgery for melanoma spares patients complications.* Many patients with intermediate-thickness melanomas (1.2 mm to 3.5 mm) routinely receive sentinel lymph node biopsy, a procedure that removes the first lymph node to which cancer cells are likely to spread. The lymph node is then checked for cancer. If cancer cells are found in this sentinel node, the patient is more likely to experience a recurrence of melanoma after surgery.

To lower the chances of recurrence in patients with cancer in sentinel nodes, removal of the remaining lymph nodes near the tumor is usually recommended; however, this more extensive surgery increases the risk for complications, particularly long-term swelling of an arm or leg from the build-up of lymph fluid in tissues, known as lymphedema. Experts have therefore questioned the value of this surgical procedure in patients with positive sentinel lymph nodes.

A large clinical trial reported in 2017 suggests that the removal of additional lymph nodes may not be necessary (this study was funded, in part, by a grant from the NCI).<sup>81</sup> At 3 years, the rate of melanoma-specific survival (the percentage of people who had not died of melanoma) was the same (86%) whether patients received additional surgery to remove lymph nodes or were only observed.

Patients who received additional surgery had a lower risk of regional recurrence, but also had more health complications. The rate of lymphedema was four times higher in the surgery group than in the observation group (24% v 6%, respectively). Given that lymph node surgery does not improve survival, it

may be possible to avoid this treatment in many patients and spare them an additional surgery with its associated complications.

### A Policy Focus: Streamlining Adverse Events Reporting for Cancer Clinical Trials

Regulations require research sponsors to report certain serious adverse events experienced by patients in a clinical trial to the FDA via an expedited process. The current challenge with reporting is the high volume of uninformative reports, which hinders patient safety, imposes a substantial toll on the FDA, research site time, and resources. In March 2017, ASCO held a workshop on streamlining adverse events reporting. Attended by stakeholders from across the cancer research community, including researchers, industry representatives, patient advocates, and officials from the FDA and the NCI, the workshop discussed ways to decrease over-reporting as well as best practices for adverse events reporting for both sponsors and research sites. Recommendations developed through this effort were published in late 2017 in *Journal of Clinical Oncology*.

*Fewer women having additional breast surgery after lumpectomy.* Performing a second surgery after initial lumpectomy for early breast cancer was previously common. Second surgery was often recommended as a result of positive or close margins, which means that some cancer cells were found along the edge of the cancer tissue removed by lumpectomy; however, there has been controversy over what constitutes a negative margin.

In 2014, the Society of Surgical Oncology and the American Society of Radiation Oncology published an evidence-based consensus statement, endorsed by ASCO, that recommended that if there are no cancer cells adjacent to any inked edge/surface of the surgical specimen, the margins should be considered negative and a second surgery is not required.<sup>82</sup>

A recent large, population-based study assessed the effect of this recommendation on the rates of breast cancer surgery (this study was funded, in part, by a grant from the NCI).<sup>83</sup> From 2013 to 2015, the rate of initial lumpectomy remained stable at 67%, but the rate of second breast surgery declined by 16%, and fewer women underwent a subsequent mastectomy. This study demonstrates the important role of clinical practice guidelines in reducing overtreatment.

*Delaying rectal cancer surgery lowers the risk of complication.* Radiation therapy before surgery lowers the risk of local recurrence in patients with rectal cancer. In the past, it was considered important to perform surgery soon after the completion of radiation therapy, but a new study in Sweden found that delaying surgery by a few weeks is safe and results in fewer complications.<sup>84</sup>

There was no difference in local recurrence between patients who received the standard short-course radiation therapy with

surgery within 1 week and those who received surgery 4 weeks to 8 weeks after either short-course radiation or long-course radiation therapy. Patients who received short-course radiation therapy with delayed surgery had a nearly 40% lower risk of complications after surgery than those who received standard short-course radiation without a delay in surgery.

Although common in Europe, short-course radiation therapy before surgery is not used in the United States, where the standard approach is chemotherapy and radiation. An ongoing clinical trial is exploring whether radiation therapy can be eliminated from the treatment of high-risk, locally advanced rectal cancer ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01515787) identifier: NCT01515787).

*Lowering radiation therapy dose for throat cancer reduces long-term complications.* HPV-associated oropharyngeal cancer responds well to treatment, but the standard radiation therapy administered with chemotherapy can lead to debilitating long-term complications. As patients with HPV-associated oropharyngeal cancer tend to be younger, they may carry the burden of these complications for decades.

Two separate clinical trials found that lowering the standard radiation dose by 15% to 20% in patients with a favorable prognosis (ie, a complete clinical response is achieved with initial chemotherapy) does not compromise survival. In the first study, the 2-year survival rate was 94% for patients who were treated with 54 Gy and 96% for those who received  $\leq 54$  Gy, and adverse effects were milder with the lower dose (this study was supported, in part, by grants from the NCI and the US Department of Health and Human Services).<sup>85</sup> At 12 months, markedly fewer patients in the lower-dose group had difficulty swallowing solids (40% v 89%, respectively) or impaired nutrition (10% v 44%, respectively) compared with patients who received higher doses of treatment. In the second study, where patients with a more favorable prognosis received a dose of 54 Gy and others received 60 Gy, cancer had not worsened for 92% of patients overall at 2 years.<sup>86</sup>

If confirmed in a larger clinical trial, these findings will lead to a change in the standard of care for patients with lower-risk, HPV-related oropharyngeal cancer (eg, those with a minimal smoking history and small tumor size). For more information about oropharyngeal cancer, visit [Cancer.Net](http://Cancer.Net).

### Recent ASCO Clinical Practice Guidelines

Clinical practice guidelines help to distill knowledge about a particular clinical issue and provide recommendations to help clinicians deliver the best treatment and care to every patient. ASCO develops its clinical practice guidelines through a rigorous, systematic review of relevant medical literature and clinical interpretation from a multidisciplinary panel of experts and patient representatives. In 2017, ASCO issued more than 14 clinical practice guidelines, guideline updates, and provisional clinical opinions (Table 4). To view ASCO guidance by clinical area, visit <https://www.asco.org/practice-guidelines/quality-guidelines/guidelines>.

**Table 4.** ASCO Clinical Practice Guidelines, Updates, Endorsements, and Provisional Clinical Opinions from January to October 2017

Publication Date	Guideline
Guideline	
January 17	Management of Small Renal Masses: American Society of Clinical Oncology Clinical Practice Guideline Summary
January 30	Screening to Prevent Invasive Cervical Cancer: ASCO Resource-Stratified Clinical Practice Guideline
February 6	Molecular Biomarkers for the Evaluation of Colorectal Cancer: Guideline From the American Society for Clinical Pathology, College of American Pathologists, Association for Molecular Pathology, and the American Society of Clinical Oncology
March 6	Use of Adjuvant Bisphosphonates and Other Bone-Modifying Agents in Breast Cancer: A Cancer Care Ontario and American Society of Clinical Oncology Clinical Practice Guideline
March 17	Primary Prevention of Cervical Cancer: American Society of Clinical Oncology Resource-Stratified Guideline
August 10	Treatment of Nonmetastatic Muscle-Invasive Bladder Cancer: American Urological Association/American Society of Clinical Oncology/American Society for Radiation Oncology/Society of Urologic Oncology Clinical Practice Guideline
September 11	Patient-Clinician Communication: American Society of Clinical Oncology Consensus Guideline
Guideline Update	
March 27	Brachytherapy for Patients With Prostate Cancer: American Society of Clinical Oncology/Cancer Care Ontario Joint Guideline Update
April 11	Potentially Curable Pancreatic Cancer: American Society of Clinical Oncology Clinical Practice Guideline Update
April 24	Adjuvant Systemic Therapy and Adjuvant Radiation Therapy for Stages I to IIIA Resectable Non–Small-Cell Lung Cancers: American Society of Clinical Oncology/Cancer Care Ontario Clinical Practice Guideline Update
July 10	Use of Biomarkers to Guide Decisions on Adjuvant Systemic Therapy for Women With Early-Stage Invasive Breast Cancer: American Society of Clinical Oncology Clinical Practice Guideline Focused Update
July 31	Antiemetics: American Society of Clinical Oncology Clinical Practice Guideline Update
August 14	Systemic Therapy for Stage IV Non–Small-Cell Lung Cancer: American Society of Clinical Oncology Clinical Practice Guideline Update
Guideline Endorsement	
February 27	Head and Neck Cancer Survivorship Care Guideline: American Society of Clinical Oncology Clinical Practice Guideline Endorsement of the American Cancer Society Guideline
Provisional Clinical Opinion	
April 25	Second-Line Hormonal Therapy for Men With Chemotherapy-Naïve, Castration-Resistant Prostate Cancer: American Society of Clinical Oncology Provisional Clinical Opinion

For additional advances in cancer treatment, please see Appendix [Table A1](#) (online only).

## ADVANCES IN PATIENT CARE

### **Communication and Coping Tools Improve End-of-Life Planning**

Having accurate information about prognosis is crucial for patients with late-stage cancer. Having conversations about the end of life helps patients set appropriate goals and potentially avoid intensive medical treatments and hospital death.

However, many patients are misinformed about or misunderstand their prognosis, and others have difficulty coping with the realization that their illness is terminal. Recent research has focused on interventions and tools that may help overcome this gap in patient-doctor communication.

In one study, a communication coaching intervention helped patients with late-stage cancer actively seek information and express preferences about their care (this study was funded, in part, by a grant from the NCI).<sup>87</sup> Oncologists in the intervention group received brief, individualized, skill-based communication training that focused on being receptive to patient questions and concerns. Patients received individualized communication coaching that incorporated a list of questions related to cancer care and end-of-life issues. Oncologists and patients in the control group did not receive any communication training or prompting.

During a subsequent office visit, nearly three times as many patients in the intervention group than in the control group (17% *v* 6%, respectively) asked about prognosis, and more than twice as many (70% *v* 33%, respectively) brought up topics that were

covered by the communication coaching, such as cancer treatment, current cancer state, and preferences about care at the end of life. Whereas validation of these results in other settings is necessary, they underscore the value of combined patient–doctor interventions to enhance communication.

New online tools are another way of helping patients plan for the end of life. In a recent study of elderly patients with chronic and/or serious conditions, 35% of those who used the interactive, patient-centered advance care planning Web site, PREPARE, along with an easy-to-read advance directive, succeeded in assembling advance planning documentation compared with 25% of those who used the advance directive alone (this study was funded by a grant from the US Department of Veterans Affairs Office of Research and Development).<sup>88</sup> Given that the Web site used in this study is free to the public and requires no physician involvement, it represents a method of improving end-of-life care with minimal health care system resource expenditure.

Research shows that certain coping strategies can help patients with incurable cancer who accurately understand their diagnosis to be terminal (this study was funded, in part, by grants from the NIH, NCI, and the National Institute of Nursing Research).<sup>89</sup> For example, patients who used positive reframing (ie, looking for something good in their situation) and active coping (ie, taking action to try to make their situation better) had improved quality of life and less depression.

It is important that doctors communicate the availability of these tools and help patients both understand and cope with advanced cancer and a terminal prognoses. A new ASCO guideline provides oncologists with recommendations regarding core communication skills that apply across the continuum of cancer care, including discussion of goals of care and prognosis, treatment

selection, and end-of-life care.<sup>90</sup> For more information on coping with cancer, visit [Cancer.Net](http://Cancer.Net).

### CancerLinQ Partners With Federal Agencies and Medical Specialty Societies

In 2017, one of the main focus areas for CancerLinQ was partnering with federal agencies, professional societies, and life sciences companies. The goal of these collaborations was to convene the cancer community around solutions for improving the quality of care for patients with cancer. By leveraging the expertise of the many stakeholders that span the care continuum, all of whom affect key decision points in a patient's care, we can help make CancerLinQ a system that encompasses all of cancer care. The effort was successful, with 10 collaborations formally signed and announced between June 2016 and June 2017 with the following organizations:

- American Academy of Physician Assistants
- American Society of Radiation Oncology
- Cancer Informatics for Cancer Centers
- College of American Pathologists
- US Food and Drug Administration
- Hematology/Oncology Pharmacy Association
- National Comprehensive Cancer Network
- National Cancer Institute
- Oncology Nursing Society
- Society of Gynecologic Oncology

The organizations with which CancerLinQ has partnered are invited to participate in the CancerLinQ Oncology Leadership Council, the official body of strategic advisors that comprise member representatives from CancerLinQ's official partner organizations and advisory groups. This is the first time that a coalition of this nature has been created and convened. As CancerLinQ creates this community of learning in cancer, these foundational partners offer incredible thought leadership and represent the importance of a team-based approach to delivering high-quality care.

### Managing Common Adverse Effects and Complications

*Radiation therapy for lung cancer increases the risk for heart problems.* Radiation has been the backbone of treatment of stage III NSCLC for three decades. Despite the known harmful effects that chest radiation can have on the heart, patients with stage III NSCLC still receive high doses of radiation because it is believed that few live long enough to experience heart complications (life

expectancy is < 2 years). A pair of studies published in 2017 challenge this notion by showing that heart problems are relatively common in this patient population and occur earlier than historically understood.

In an analysis of patients who were treated in six clinical trials from 1996 to 2009, 21% of those who received a high dose of radiation ( $\geq 20$  Gy) developed symptomatic heart problems within 2 years (this study was funded by a grant from the NIH).<sup>91</sup> Heart problems were independently linked to high doses of radiation and underlying risk (eg, smoking and cardiovascular disease).

A second analysis of patients who were treated in four clinical trials from 2004 to 2013 demonstrated similar results; 11% developed severe heart problems within 2 years (this study was funded by a grant from the NIH).<sup>92</sup> As in the other study, patients who received a higher radiation dose and/or had pre-existing heart disease were more likely to develop heart problems. Furthermore, both cancer worsening and heart problems were linked to shorter survival.

These findings will inform treatment and survivorship discussions between physicians and patients with stage III NSCLC. When selecting radiation dose, controlling tumor growth should be balanced with minimizing the risk for heart problems, particularly in patients with an underlying risk of heart disease.

A recent guideline from ASCO recommends that, before the start of therapy, doctors should discuss the potential for heart problems with patients who are at increased risk for such complications and establish a tailored and detailed plan to monitor them during and after cancer treatment.<sup>93</sup>

*Single radiation treatment relieves symptoms of spinal cord compression.* As many as one in 10 people with advanced cancer develops spinal cord compression. This condition is a major detriment to quality of life, causing back pain, numbness, tingling, difficulty or inability to walk, and sometimes bowel or bladder incontinence. Radiation therapy can prevent or relieve these symptoms, but it typically requires multiple trips to the clinic for treatment.

Research presented in 2017 demonstrated that a single radiation treatment may be sufficient for patients with a short life expectancy.<sup>94</sup> In a large clinical trial, one-time radiation treatment was as effective as 5 days of treatment in terms of helping patients stay mobile, and median survival was not different between the two groups (approximately 3 months). Shortening radiation therapy allows patients with cancer-related spinal cord compression to spend less time in the hospital and more time doing things they enjoy.

*For cancer-related fatigue, exercise and psychological support work best.* Cancer-related fatigue is different from feeling tired after staying up too late. It is a persistent feeling of physical, emotional, or mental exhaustion that interferes with one's daily activities and does not improve with rest. Most people who receive cancer treatment experience fatigue, and approximately one third of survivors of cancer experience fatigue that lasts for years after finishing treatment.

Numerous approaches for treating cancer-related fatigue have been tested, with variable outcomes; therefore, it has not been clear which treatments work best. An analysis of 113 randomized clinical trials compared the four most commonly recommended

treatments, which are exercise, psychological intervention, combined exercise and psychological intervention, and medication (this study was funded in part by grants from the NIH).<sup>95</sup>

Exercise, psychological support, and the combination of the two approaches improved cancer-related fatigue during and after cancer treatment. Benefits of these treatments were greater for patients with nonmetastatic disease and varied by intervention mode and timing; however, medications were much less effective than behavioral interventions.

These findings confirm a large body of literature in the field and suggest that exercise and psychological interventions should be used before pharmaceutical interventions, which provide minimal benefit. These recommendations are relevant to many patients with cancer.

ASCO recommends that health care providers assess the patient's level of fatigue at diagnosis and repeat this assessment yearly and at any time there are symptoms of fatigue throughout treatment and into recovery.<sup>96</sup> For more information about cancer-related fatigue, visit [Cancer.Net](http://Cancer.Net).

### ASCO Launches Center for Research and Analytics

In June 2017, ASCO announced the launch of its new Center for Research and Analytics (CENTRA) to make an array of cancer data available to the oncology community and provide consultation and support for research and analysis. The CENTRA team will help analyze and build an evidence base that can help to support cancer policy development, advance the practice of oncology, and improve cancer care for patients. This supports ASCO's continuing commitment to helping to advance the field of oncology and improve cancer care through the generation and application of high-quality evidence.

Requests can be made through CENTRA for data from ASCO sources, such as our quality programs, annual census of oncology practices, and scientific meeting abstracts and presentations. All research requests will be evaluated before being fulfilled.

For more information or to submit requests, please contact [CENTRA@asco.org](mailto:CENTRA@asco.org).

### Patient Engagement Leads to Improved Care

*Web-based symptom reporting extends survival.* The value of patients reporting their own outcomes is increasingly recognized in oncology, and there is interest in integrating patient-reported outcomes into routine practice. A recent study demonstrated that a Web-based, patient-reported outcomes tool can help patients with advanced cancer live longer.<sup>97</sup>

With the standard approach of assessing symptoms only during office visits, the health care team can be unaware of patients' symptoms up to half of the time. In a clinical trial, the Web-based tool enabled patients to report common symptoms in real time and triggered alerts to clinicians if symptoms worsened (this study was

supported by ASCO's Conquer Cancer Foundation). When appropriate, clinicians took action to relieve symptoms, such as lowering the chemotherapy dose or providing supportive care.

Patients with metastatic cancer who used the tool while receiving chemotherapy lived a median of 5 months longer than those who did not use the tool (31 months v 26 months, respectively). This improvement in survival was greater than that associated with nearly all cancer drugs that received FDA approval in 2016.

Researchers previously reported that the use of the same tool was associated with better quality of life and fewer visits to the emergency room and hospitalizations. The findings confirm that patient-reported outcomes should be the standard of care for patients with late-stage cancer. A nationwide clinical trial that uses an updated tool that works on both personal computers and mobile devices is under way in community practices across the United States.

*After cancer diagnosis, an online support program lowers distress.* Patients experience major distress when they first learn of their cancer diagnosis. Yet amid all the tests, treatment appointments, and family or work decisions, little attention is paid to one's psychological and emotional well-being. In fact, as a result of patients' time constraints and the lack of availability and resources for psychological support, few patients who are newly diagnosed with cancer receive any psychological support.

To address this need, researchers are looking into leveraging Internet-based technologies to provide support to more patients and improve their quality of life. In a recent study, an 8-week Web-based stress management program that was designed by psychologists and oncologists improved quality of life and lowered distress for patients who were newly diagnosed with cancer.<sup>98</sup>

The program covered different topics, such as bodily reaction to stress, cognitive stress reduction, feelings, and social interactions. For each weekly topic, participants received written and audio information, then completed exercises and questionnaires.

The study demonstrated that delivering psychological support via an Internet-based program is feasible, but more research is needed to refine and scale up such an approach for broad use. Researchers already have plans to translate the program into other languages (it is currently available only in German).

*Crowdsourcing advances cancer research.* Progress against rare cancers is often slow because of a combination of scarce funding and a limited availability of patients and tumor samples for research. An attractive solution to this problem is crowdsourcing. More and more people with rare and common cancers today have the opportunity to rapidly and directly affect research by sharing their tumor tissue samples and medical and/or genetic information to help others with the same or similar diseases. In return, researchers share what they learn with participants.

The Metastatic Breast Cancer Project collects health records and tumor and saliva samples to learn why some patients respond differently to cancer treatments than others. The project engages patients to participate via social media, newsletters, blogs, and advocacy organizations.

Two other such projects focused on sarcoma are run by researchers with the support of patient advocacy organizations, the Angiosarcoma Project and the Leiomyosarcoma Direct Research.

Another emerging type of crowdsourced research engages members of the general public, so-called citizen scientists, to gather ideas, design studies, and perform research-related tasks, such as

analysis of scientific images or quantitative data. This approach is particularly helpful in pathology research studies that require manual review of a large quantity of images. The Cell Slider project recruited approximately 100,000 people to classify images of breast tumor tissue according to estrogen receptor status. To assess the volunteers' performance, researchers compared their classification with that of trained pathologists and found that citizen scientists were able to classify tumors with high accuracy.<sup>99</sup> For additional notable advances in patient care, please see Appendix Table A1.

## LOOKING TO THE FUTURE

### ***New Type of Medicine Tackles Undruggable Molecular Targets***

Although targeted therapies have had a profound effect on cancer medicine, only approximately 20% of proteins in cancer cells can be targeted by currently available medicines. Many of the undruggable targets include important molecules in pathways that suppress (eg, TP53 and APC) or promote (eg, RAS and MYC) tumor growth. One of the reasons these targets are undruggable is that, historically, it has been difficult to block these pathways with small molecules, and protein drugs do not easily penetrate the cell.

A new class of drugs, known as stapled peptides, has emerged as a promising way to target protein-protein interactions. These small proteins have an artificial chemical bridge, or staple, that holds them in a specific shape that allows them to penetrate the cell.

In an early clinical trial, researchers demonstrated for the first time that a stapled peptide is effective in patients.<sup>100</sup> The peptide targeted the interaction between MDM2 and MDMX-TP53 in patients with solid tumors and lymphoma without p53 mutations. The treatment, ALRN-6924, stalled cancer growth in 45% of 55 patients. A larger clinical trial is under way ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02264613) identifier: NCT02264613).

### ***Emerging Role for Precision Medicine in Cancer Prevention***

The concept of precision medicine as applied to cancer prevention is in its nascent stages. In this first phase, scientists are focusing on inherited cancer syndromes, such as *BRCA*-related breast and ovarian cancers and Lynch syndrome.

For patients with inherited genetic susceptibility to cancer, the hope is to one day replace crude, one-size-fits all cancer risk reduction approaches, such as preventive surgery, with personalized approaches that take into account not only a person's genetic makeup and family history, but also the composition of microbes in their body, their diet, lifestyle, and environmental factors.<sup>101</sup>

Scientists are only beginning to understand how the complex interplay of all these factors raises or lowers the chance of developing cancer in an individual with an inherited cancer gene mutation. It is also not clear why changes in genes with broad functions, such as the DNA repair and MMR genes, predispose people for certain, but not all cancers.

Large-scale genomics studies are providing insights by which to fine-tune cancer risk assessment for each person. For example, it seems that certain changes in mitochondrial DNA lower the risk of breast cancer in patients with *BRCA* mutations. Genomic information, along with reproductive and family history, lifestyle,

and other factors, may help patients decide whether and when to have preventive surgery.

Scientists are also exploring the possibility of using immune-based approaches, such as vaccines for cancer prevention in healthy people with cancer predisposition syndromes.<sup>102</sup> The idea is to harness the immune system to recognize and eliminate pre-malignant cells on the basis of their molecular characteristics. With the new national investment in cancer prevention through the Cancer Moonshot initiative and cutting-edge technologies, such as sequencing the genomes of individual cells, the opportunity to advance this field is closer than ever.

### ***Understanding Health Disparities: Path to Better Care For All***

Cancer is becoming one of the most pressing health care challenges worldwide. Between 2005 and 2015, the number of patients with cancer increased worldwide by 33%.<sup>103</sup> According to the Global Burden of Disease study, issued in late 2017, cancer is the second leading cause of death from noncommunicable diseases, which cause 72% of deaths worldwide.<sup>25</sup>

Whereas many countries have experienced decreases in cancer mortality over the last decade, cancer deaths increased in Sub-Saharan Africa and certain other regions lacking in health care infrastructure (this study was funded in part by a grant from the NIH).<sup>103</sup> Seven of 10 cancer deaths occur in regions of Africa, Asia, and Central and South America, where access to cancer screening and treatment is limited.<sup>104</sup>

Even within high-resource countries, such as the United States, certain communities experience greater cancer incidence, shorter survival, and more deaths from cancer. During the last 60 years, socioeconomic, education, and racial/ethnic inequities in cancer mortality have persisted and even widened in some cases.<sup>105</sup>

#### **Impact of Cancer Care Cost**

Among Americans who have never had cancer, 35% are not confident they would receive timely, best-in-class care if diagnosed with cancer in the future. Of serious concern, 27% of Americans who either had cancer themselves or have/had a family member with cancer have taken specific actions to lower treatment costs:

- 9% have skipped doctor appointments;
- 8% have refused treatment;
- 8% have postponed filling or not filled prescriptions;
- 8% have skipped doses of prescribed medications; and
- 7% have cut pills in half.

(ASCO's National Cancer Opinion Survey, 2017).

Recently published studies reveal that the root causes of cancer disparities in the United States are complex. Researchers found that black patients across all socioeconomic groups have higher cancer mortality than white patients. Another study found that people from the poorest communities were more likely to be diagnosed with advanced cancer, regardless of whether they had health insurance.

### ASCO Issues Recommendations for Reducing Cancer Disparities Among Sexual and Gender Minority Populations

Sexual and gender minority (SGM) populations, including individuals who are lesbian, gay, bisexual, transgender, and intersex, bear a disproportionate cancer burden that stems from several factors, such as lower rates of cancer screening and a hesitancy on the part of SGM patients to disclose their sexual orientation to providers because of a fear of stigmatization. On April 3, 2017, ASCO issued recommendations to address the needs of SGM populations as they relate to cancer. The recommendations, published in a policy statement in *Journal of Clinical Oncology*, are designed to focus attention on the challenges that face the SGM community, including discrimination and greater risk of anxiety and depression, resulting in disparate care. The statement also provides concrete steps that can help minimize health disparities among SGM individuals.

### A Policy Focus: Giving Medicaid Patients Equal Access to Clinical Trials

Most private insurance plans and Medicare are required to cover the routine costs of care for patients who participate in clinical trials. Routine care includes items and services that a payer would cover for a patient who is not enrolled in a clinical trial, such as office visits, radiology exams, and laboratory tests; however, Medicaid is not required to cover these routine costs for patients.

For researchers to understand how different populations respond to cancer treatment and address disparities in cancer outcomes, all types of patients should have the opportunity to participate in cancer trials. Unfortunately, patients from racial and ethnic minority groups that are over-represented in the Medicaid program make up just a small subset of clinical trial participants.

ASCO strongly encourages policymakers to guarantee that Medicaid covers routine care costs for patients in clinical trials so that more patients with Medicaid can participate in cancer research.

In addition, patterns of disparity have been changing. For example, during the 1950s, black people had lower all-cancer mortality than did white people, but since the 1960s, all-cancer mortality rates have been significantly higher for black people than for white people across all socioeconomic groups. Differences are particularly pronounced for some cancers. Within each socioeconomic group, black women have a two times higher cervical cancer mortality and a 50% higher breast cancer mortality rate than white women, and black men have a two times higher prostate cancer mortality rate than white men.<sup>105</sup>

Socioeconomic disparities have also reversed over time. In 1950, people in the most-deprived socioeconomic group had a 27% lower cancer mortality rate than those in the most affluent group, but by 2010 to 2014, the most deprived group had a 22% higher cancer mortality than their most affluent counterparts.<sup>105</sup>

Although patients from disadvantaged communities benefit most from health insurance coverage, insurance alone does not overcome the mortality gap. In one study, patients in the poorest communities were more likely to have advanced cancer at diagnosis and less likely to receive cancer-directed surgery than those from the least disadvantaged communities, regardless of health insurance status (this study was funded, in part, by a grant from the NIH/NCI).<sup>106</sup> Another analysis demonstrated that among people with no health insurance, black patients had rates of cancer mortality that were similar to those of white patients, but had higher mortality rates among either Medicaid or private insurance groups.<sup>107</sup>

Even with access to health care, patients may not seek care for many reasons that include having insurance but no health care available nearby, not knowing how to access the health care system, or lack of trust in the health care system.

Other research suggests that socioeconomic disparities in cancer death rates may, in part, be a result of modifiable behaviors that increase the risk of cancer. The 2015 National Health Index Survey showed that prevalence of smoking, obesity, physical inactivity, and inadequate intake of fruit and vegetables was higher

among people with lower education and income levels, and rates of cancer screening were lower.

Taken together, this body of research suggests that addressing cancer disparities and achieving equity calls for multifaceted approaches that are focused on efforts to improve prevention, screening, and access to high-quality cancer care.

### A Policy Focus: Addressing Health Disparities in Cancer Care

Significant cancer health disparities continue to exist in certain populations. Race, ethnicity, socioeconomic status, and geography all affect patient health outcomes, and racial and ethnic minorities and individuals of lower socioeconomic status experience worse cancer outcomes.

To address this issue, ASCO, with the American Association for Cancer Research, the American Cancer Society, and the NCI, released a joint statement to foster cooperation across the cancer research community to ensure that all patients, regardless of demographics, socioeconomic status, or the communities in which they live, benefit from cancer research (the statement was published in *Journal of Clinical Oncology*).<sup>108</sup>

The statement called for defining and improving data measures and tools for cancer disparities research, addressing disparities in cancer incidence, addressing cancer survival disparities, improving community engagement in cancer research, and redesigning clinical trials to acknowledge and address cancer disparities.

**Corresponding Authors:** Andreas F. Hottinger, MD-PhD, Departments of Clinical Neurosciences, and Oncology, Centre Hospitalier Universitaire Vaudois (CHUV), Rue du Bugnon 46, 1011 Lausanne, Switzerland ([andreas.hottinger@chuv.ch](mailto:andreas.hottinger@chuv.ch)); Roger Stupp, MD, Department of Oncology, University Hospital Zurich, Raemi-Street 100, 8091 Zurich, Switzerland ([roger.stupp@usz.ch](mailto:roger.stupp@usz.ch))

Tumor treating fields (TTFields) are low-intensity electric fields alternating at an intermediate frequency (200 kHz), which have been demonstrated to block cell division and interfere with organelle assembly. This novel treatment modality has shown promise in a variety of tumor types. It has been evaluated in randomized phase 3 trials in glioblastoma (GBM) and demonstrated to prolong progression-free survival (PFS) and overall survival (OS) when administered together with standard maintenance temozolomide (TMZ) chemotherapy in patients with newly diagnosed GBM. TTFields are continuously delivered by 4 transducer arrays consisting each of 9 insulated electrodes that are placed on the patient's shaved scalp and connected to a portable device. Here we summarize the preclinical data and mechanism of action, the available clinical data, and further outlook of this treatment modality in brain tumors and other cancer indications.

### Preclinical Data and Mechanism of Action

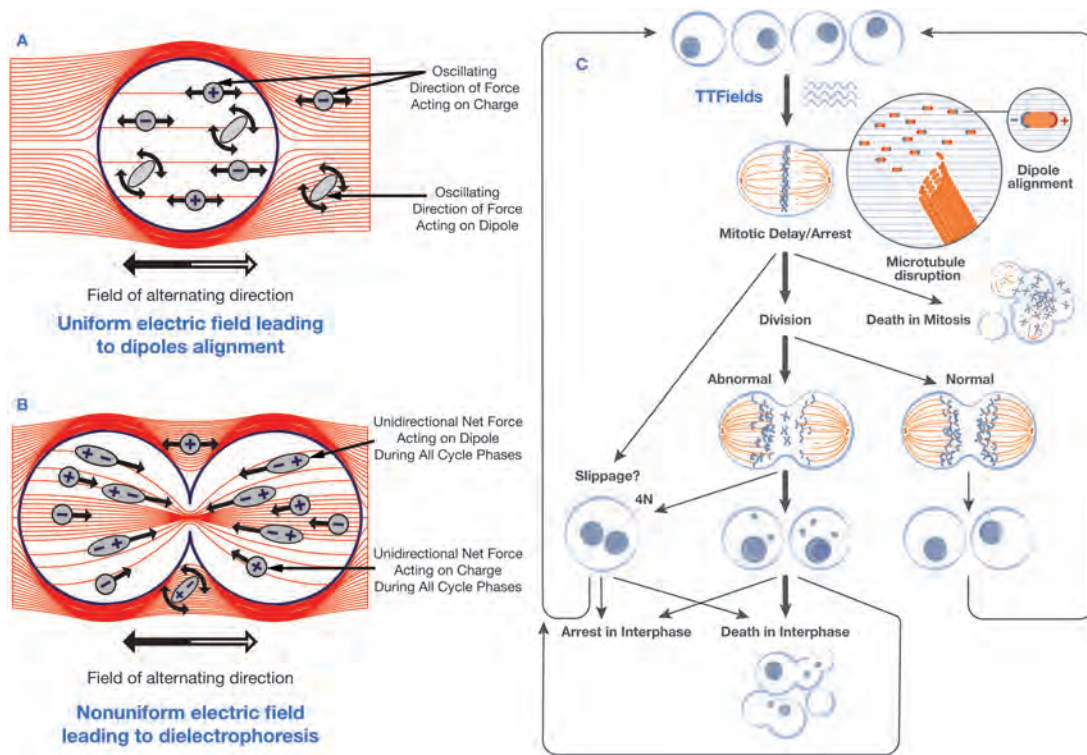

Living cells consist of charged or polar molecules and ions and thus are responsive to electrical fields and currents. Electric activity of cells plays a key role in many essential biological processes including cell division. Cellular processes can be influenced by electric fields. The overall effect will depend upon the magnitude of the potential difference between the 2 electrodes (field intensity) and the frequency: at very low frequencies (<1 kHz) excitable cells such as neurons or myocytes will be depolarized.<sup>1</sup> Cardiac pacemakers or deep brain stimulators work in this range of frequency. At very high frequencies (>MHz), heat is generated in the tissues due to dielectric loss. This property is mainly used for radiofrequency ablation or diathermy treatments.<sup>2</sup> The alternating frequency of electrical fields at intermediate frequencies (range, 10–1000 kHz) is too fast to induce cell depolarization and induces no or only minimal heat by dielectric loss. In the past, these frequencies were considered to have no interaction with biological processes.<sup>3</sup> Nevertheless, a number of effects have been observed in biological tissues such as microscopic particle alignment,<sup>4</sup> cell rotation,<sup>5</sup> and transient pore formation in cell membranes.<sup>6</sup> At low intensities (2V/cm) and intermediate alternating frequencies (between 100–300 kHz), Kirson and Palti et al. demonstrated a specific inhibiting effect on cell division in cancer cell culture models.<sup>7</sup>

Tumor treating fields (TTFields) are alternating, low-intensity, intermediate frequency electric fields that aim to disrupt cell division and inhibit tumor growth. In initial experiments, exposure of a variety of tumor cell lines to TTFields was shown to exert a profound growth inhibitory effect by inducing cell cycle arrest and apoptosis, while no effect was induced on non-dividing cells.<sup>7</sup> These in vitro observations could also be confirmed in vivo in mice and rabbit tumor models.<sup>8</sup> Further studies demonstrated that the growth inhibitory effect is largely mediated by interference on the mitotic spindle apparatus. TTFields will target proteins with large dipole moments (ie, septins and the spindle microtubules, components essential in the metaphase and anaphase stages of the mitotic cycle for separation and equal distribution of chromosomes).<sup>9,10</sup> Furthermore, inhibition of the polymerization of microtubules interferes with proper assembly of the mitotic spindle apparatus. In telophase, during cytokinesis the hourglass shape taken by the daughter cells that are about to separate induces a nonuniform electric field that is strongly enhanced at the level of the furrow region (→ [fig. 1](#)). This results in dielectrophoretic forces that may attract charged molecules from the cytosol and compromise normal cytokinesis.<sup>7</sup> The antitumoral effect results from disruption of the microtubular assembly during mitosis, blocking formation of the mitotic spindle apparatus and blocking separation of the 2 daughter cells.<sup>9</sup> This effect also results in abnormal chromosomal segregation and reduced clonogenic potential of the cell's progeny.<sup>10</sup>

**Fig. 1.** Mechanisms of action of tumor treating fields in and around quiescent and dividing cells. Inside quiescent cells (1A), the field is uniform, and the oscillating electric forces result only in “vibration” of ions and dipoles (the forces associated with each half cycle are denoted with white and gray arrows). In contrast, the nonuniform field within dividing cells (1B) induces forces pushing all dipoles toward the furrow. [reprinted with permission from ref. 12] 1C: Tumor treating fields (TTFields) exert directional forces and result in abnormal spindle formation and subsequent mitotic arrest or delay, possibly due to improper attachment of chromosomes to the spindle fibers. Cells can die in mitotic arrest or progress to cell division leading to abnormal aneuploid progeny (highlighted by bold arrow). Abnormal daughter cells die in the subsequent interphase, undergo a permanent arrest or proliferate through additional mitosis where they will be subjected to further TTFields assault. [adapted with permission, refs. 11 and 12]

Animal models of various tumors, including glioblastoma (GBM), non-small cell lung cancer, pancreatic cancer, and malignant melanoma confirmed the inhibition of tumor growth or metastatic seeding when externally applied TTFields were delivered at the appropriate frequencies.<sup>11</sup> As an example, an experimental model of rats with intracranially inoculated GBM cells treated with TTFields at a frequency of 200 kHz over 6 days showed smaller tumors compared with untreated rats.<sup>12</sup> The inhibitory effect was significantly increased when 2 or more, rather than 1 field directions were used.<sup>12</sup> Importantly, synergistic antitumor activity was demonstrated when TTFields were applied in conjunction with cytotoxic chemotherapy with paclitaxel, doxorubicin, cyclophosphamide, or dacarbazine (DTIC).<sup>13</sup>

In summary, TTFields will block the mitotic cell cycle, in particular during metaphase, anaphase, and telophase. This will result in cell cycle arrest or delay in cell division and interfere with organelle assembly, particularly the spindle apparatus (fig. 1 C). The consequences are inadequate cell division and unequal chromosome distribution. Ultimately, cells will die in apoptosis. In order to have an optimal treatment effect, the field intensity and frequency needs to be adapted to the tumor type and cell properties (eg, cell size). The optimal frequency to maximize the antitumor effect is inversely

correlated with cell size and when the incident angle of the electrical field is perpendicular to the mitotic plate.<sup>7</sup>

As the cell division may occur at any time, prolonged exposure to the electrical fields is required for maximal effect. For the delivery of TTFields, a portable and battery-powered device has been developed (→ fig. 2). The electric field is applied to the brain through 4 transducer arrays with 9 insulated electrodes each and continuous temperature sensing fixed to the patient's shaved scalp.

## Clinical Experience:

### *Glioblastoma as a Proof of Concept Model*

In the very first clinical application, TTFields treatment was applied to patients with cutaneous metastases of melanoma or breast cancer. Tumor shrinkage or even complete disappearance was demonstrated.<sup>12,14</sup> However, metastatic cancer is a systemic disease, thus most effects of application of TTFields would be expected to be seen in diseases or situations where primarily locoregional control is warranted. Primary brain tumors—and notably glioma—rarely metastasize; recurrence in the brain is the predominant cause of treatment failure and was chosen as the first disease in which the effect of TTFields could be investigated prospectively.

**Fig. 2.** Tumor treating fields (TTFields) device (2nd generation Optune) and its clinical use TTFields are administered by 4 transducer arrays placed on the shaved scalp and connected to a portable device generating 200 kHz electric fields within the brain. The position of the transducer arrays are determined by the localization of the tumor using a mapping software (NovoTal™). (Photo with permission from the patient)

In a computational model, the optimal frequency of TTFields for GBM was found to be in the range of 200 kHz. The field strength should be  $\geq 1$  V/cm. These TTFields are able to penetrate into the deep brain tissue from the surface of the scalp. The computational model also revealed inhomogeneous fields with intensification of the field strength near the ventricles as a result of the high conductivity of the cerebrospinal fluid. Necrotic areas and edematous regions also showed high conductivity of the TTFields. In contrast, areas with high cellularity showed lower conductivity.<sup>15</sup>

Following the demonstration of feasibility in a small pilot trial, the clinical merits of this innovative cancer treatment were evaluated in 2 pivotal randomized trials in recurrent (EF-11) and newly diagnosed (EF-14) GBM. In our summary, herein we always refer to the results of the intent-to-treat population (ITT); for details on the predefined per protocol populations, the reader is kindly directed to the respective original publications<sup>16,17</sup> (→ table 1).

## TTFields in Recurrent Glioblastoma

### The EF-11 Trial

For this trial, GBM patients with progressive or recurrent disease after initial treatment with radiotherapy and TMZ chemotherapy were eligible. Patients may have received several lines of prior chemotherapy. A total of 237 patients were then randomized 1:1 to either the novel TTFields therapy (120 patients) or to the best available treatment (117 patients) according to the local oncologist's best choice (active control, fig. 3A). The primary endpoint of the trial was OS. Patients' median age was 54 years, with a median KPS of 80% (range, 50–100%). Eighty-eight percent of patients had received 2 or more lines of prior chemotherapy including prior bevacizumab in 18% of patients. With a median survival of only 6.6 and 6.0 months in the TTFields and the control arm, respectively (hazard ratio: 0.86 [95% CI, 0.66–1.12],  $P=0.27$ ) and a 1-year survival rate of only 20% in both groups, the trial failed to demonstrate superiority over “established” or commonly used chemotherapy

**Table 1.** Results of EF-14 & EF-11 trials

Trial	Treatment arm	Number of patients	Progression-free survival		Overall survival		
			Median	at 6 months	Median	at 1 year	at 2 years
EF-14: newly diagnosed [Interim data set]	TTFields & TMZ	210 (466 total)	7.1 mo*	57%	19.6 mo	75%	43% (36–50)
	Maintenance TMZ	105 (229 total)	4.0 mo*	34%	16.6 mo	69%	29% (21–39)
	Hazard ratio		0.63 (CI, 0.43–0.89)		0.74 (CI, 0.56–0.98)		
	P value		< 0.01 (stat. significant)		0.0004 (stat significant)		
EF-11: recurrent GBM	TTFields	120	2.2 mo.	21%	6.6 mo*	20%	8%
	chemotherapy†	117	2.1 mo.	15%	6.0 mo*	20%	4%
	Hazard ratio		0.81 (CI, 0.60–1.09)		0.86 (0.66–1.22)		
	P value		0.13 (not significant)		0.27 (not significant)		

Abbreviations: CI, 95% confidence interval; mo, months; TMZ, temozolomide; TTFields, Tumor Treating Fields; EF, electrical fields

\*: primary trial endpoint, other values are predefined secondary endpoints

**Fig. 3.** Design of the pivotal trials in GBM. A: EF-11 Trial Design B: EF-14 Trial Design

regimens. The median duration of TTFields administration was only 2.3 months (95% CI, 2.1– 2.4) with tumor progression as the primary reason for discontinuation of treatment. Still it showed objective responses with TTFields alone in 14% of patients compared with 9.6% in the control arm. The study demonstrated safety and feasibility of TTFields in a large multicenter setting.

The design and conduct of the EF-11 trial had some inherent limitations: numerous prior treatment lines were allowed and led to a heterogeneous patient population. More than 40% of patients were included after the third recurrence, including many patients who had failed prior bevacizumab therapy. Thus, most patients suffered from very advanced disease and had only few available treatment options and limited life expectancy. In the absence of a commonly accepted standard treatment for recurrent GBM, the control patients

were to receive the best available systemic therapy according to the current local practice. The heterogeneity of treatments prescribed to the control patients reflects this fact: about one-third of the control patients received bevacizumab alone or in combination, 25% nitrosoureas, and 11% re-exposure to TMZ. A number of patients were discontinued from TTFields therapy very early (after <1 month of therapy), presumably due to absence of a treatment response (rather than true tumor progression) based on skepticism of the investigators. It is known that TTFields take a prolonged period of time until its effects can be clinically demonstrated or that delayed responses may occur after initial radiological tumor growth; thus, some patients may have discontinued TTFields treatment prematurely.

Based on the results of the EF-11 trial, the US Food and Drug Administration (FDA) felt that these results provided reasonable

assurance that the benefits of TTFields outweigh its risks when administered as monotherapy in place of standard medical therapy and therefore approved TTFields in 2011 (<http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm251669.htm>).

### *TTFields in Daily Practice: PriDE Dataset*

After FDA approval, TTFields became commercially available in the United States, and Mrugala et al summarized the daily practice experience on 457 patients treated at 91 US institutions (Patient Registry Dataset; PriDe).<sup>18</sup> Interestingly, patients' age and performance status were similar in this dataset and in the EF-11 trial; however, treatment with TTFields was initiated much earlier in the course of the disease. One-third of patients were treated at first recurrence (compared with 9% in the EF11 trial). Overall, median survival was 9.6 months, and the subgroup of patients who were treated at first recurrence (n=152) had a median survival of 20 months.<sup>18</sup>

### *TTFields in Newly Diagnosed GBM (EF-14 Trial)*

This open label phase 3 study in patients with newly diagnosed GBM was initiated while the trial for recurrent disease was still ongoing. For practical reasons (interference of the electrodes during radiotherapy), patients had to be randomized only after completion of standard concomitant TMZ chemoradiotherapy to standard maintenance TMZ chemotherapy (for 6–12 cycles) with or without concomitant administration of TTFields (fig. 3B). The primary endpoint was PFS, and OS was a powered secondary endpoint. Eligible adult patients (KPS  $\geq$  70%, supratentorial tumor location) had to be progression-free after the end of chemoradiotherapy, thus excluding the patients with the worst prognosis. After stratification by extent of resection (biopsy, partial resection, gross total resection, determined on MRI 24–48 hours postsurgery) and MGMT status (methylated, unmethylated, unknown) patients were randomized at a ratio of 2:1 within 3–7 weeks from the last day of radiation. Patients assigned for TTFields therapy received additional instruction and technical support for the use of the device by a device specialist (technician) during the first weeks of treatment and thereafter with monthly visits. This support was limited to technical aspects of the device and assistance with the application of arrays.

A total of 695 patients from 83 centers across the world were included between July 2009 and November 2014. More than half of the patients came from the United States. The medical follow-up was similar in both treatment arms. It included monthly clinic visits for complete physical examination and blood hematology and chemistry analyses. A mini-mental status examination (MMSE), quality of life evaluation (EORTC QLQ-C30 questionnaire and the brain-specific module BN-20) were performed at baseline and every 3 months thereafter.<sup>19,20</sup> MRI and disease assessment using the Macdonald criteria were to be performed every 2 months. All treatment-related clinical decisions were based on local interpretation of imaging; however, a blinded central imaging and disease assessment review determined the date of progression. Patients experiencing tumor progression were offered second-line treatment according to local practices. Patients were allowed to continue TTFields treatment beyond first progression

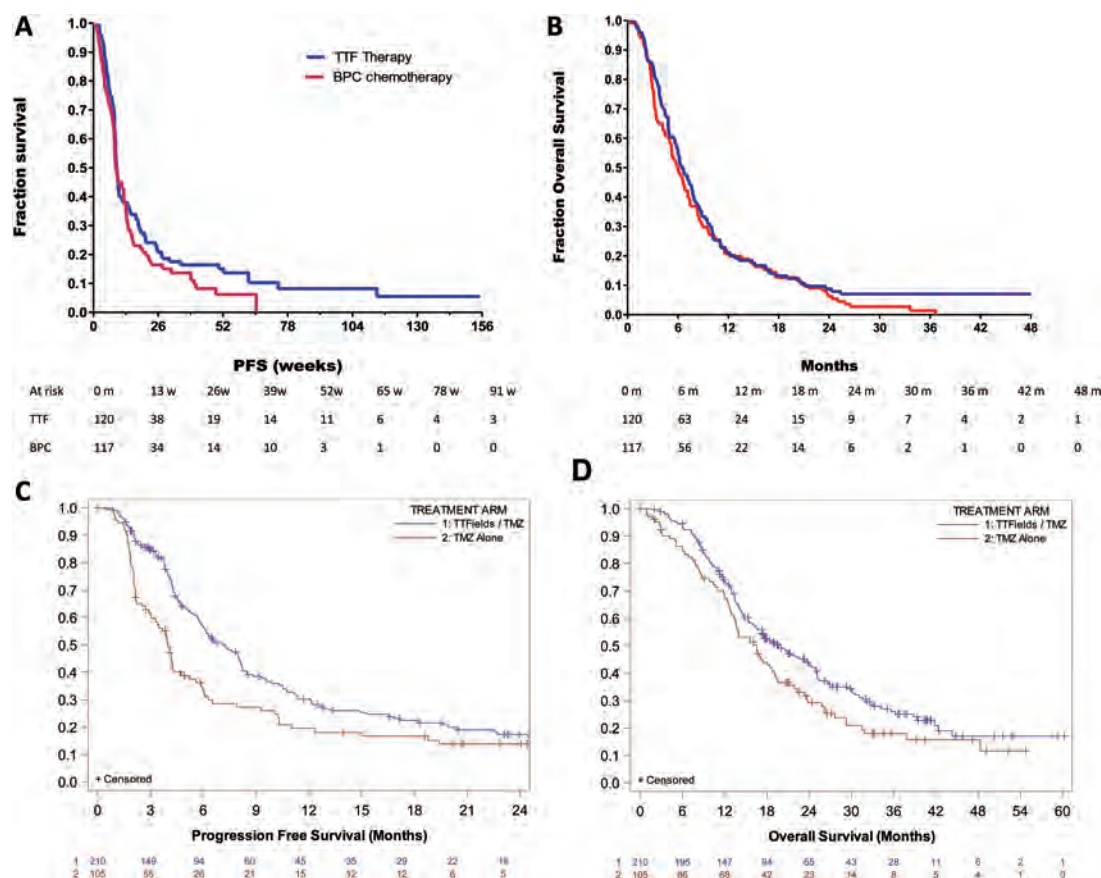

based on the prior experience of pseudoprogression and delayed responses. For the purpose of the trial, the date of first progression, as assessed by the independent review panel, was considered the primary endpoint.

The baseline patient characteristics were well balanced between the 2 groups. In both groups, 66% were male, and the median age at inclusion was 57 years (range, 20–83y), and the median KPS was 90%. Sixty-four percent of patients underwent gross total resection, and 11% had biopsy only. Central MGMT gene promoter methylation analysis was available for 72% of patients. MGMT was methylated in 39% of patients in the TTFields/TMZ group and in 41% of the control TMZ group. The median time from end of radiation therapy to randomization was 36 and 38 days in the TTFields and control groups, respectively. The median time from randomization to initiation of TTFields was 5 days. Median time from diagnosis of GBM to randomization was 3.8 months in both groups (ranges, 2.0–5.7 and 1.4–5.7 months in the treatment and control groups, respectively). Of note, 53% of patients were randomized after initiation of the first cycle of TMZ (as allowed by the protocol). Per protocol, TTFields treatment was continued up to the second progression in two-thirds of the patients; the median duration of treatment with TTFields was 9 months (range, 1–58 mo). Three-quarters of patients receiving treatment with TTFields were adherent to therapy as prescribed (ie, wearing the device  $\geq$  18 hours per day on average during the first 3 treatment months) (n=157/210).

At a prespecified interim and futility analysis to be performed once the first 315 randomized patients reached a minimum follow-up of 18 months, a significant improvement in progression-free and overall survival was seen; consequently the independent data monitoring committee recommended that the trial be terminated early for success and that patients be allowed to cross over to the TTFields arm. In the interim analysis, the ITT median PFS was increased by 3.1 months in the TTFields group with a median PFS of 7.1 months (95% CI, 5.9–8.2 mo) compared with 4.0 months (95% CI, 3.3–5.2 mo) in the control group (HR, 0.62 [98.7% CI, 0.43–0.89];  $P=.001$ ). As a direct consequence, patients in the control group received a median of 4 cycles of TMZ (range, 1–24), whereas patients in the TTFields group received a median of 6 cycles (range, 1–26) of TMZ. Median OS from randomization (ITT) was 19.6 months (95% CI, 16.6–24.4 mo) in the TTFields plus TMZ group compared with 16.6 months (95% CI, 13.6–19.2 mo) in the TMZ control group (HR: 0.74 [95% CI, 0.56–0.98];  $P=.03$ ). The percentage of patients alive at 2 years following enrollment was 43% in the TTFields/TMZ group and 29% in the TMZ alone group ( $P=.006$ )<sup>17</sup> ( $\rightarrow$  fig. 4). At first progression, 67% of the patients in the TTFields/TMZ group received a second-line therapy compared with 57% of patients in the TMZ control group. The type of salvage chemotherapy offered was balanced between the 2 groups: about 40% of second-line therapies included bevacizumab and about 40% nitrosoureas.

Preliminary subgroup analyses showed that the positive effect observed on PFS and OS by the addition of TTFields was not restricted to any subgroup of patients: in particular neither age, performance status, MGMT methylation status nor extent of resection was predictive for a better treatment

**Fig. 4.** Progression-free and overall survival in EF-11 (A&B) & EF-14 (C&D) trials. EF-11 trial: Progression-free survival (A) and overall survival (B) of the intent-to-treat population. Hazard ratio for overall survival: 0.86 (CI, 0.66–1.12,  $P=0.66$ ) [Reprinted with permission from ref, 16] Progression-free survival (C) and overall survival (D) of the intent-to-treat population in the EF-14 trial (interim data set). Hazard ratio for progression 0.63 (95%CI 0.43–0.89,  $P<0.01$ ); for survival 0.74 (CI 0.56–0.98,  $P=0.0004$ ). [Reprinted with permission, ref. 17]

effect. However, the sample size of the interim dataset may not be large enough to identify meaningful subgroups, and detailed subgroup analyses are to be performed on the final and validated dataset. Due to the 2:1 randomization, the control arm comprised only 105 patients, which limited the ability to perform formal subgroup analyses. In the final dataset, the control group will comprise 229 patients. Before publication of the interim analysis, the overall dataset of 695 randomized patients was statistically scrutinized. It was concluded that the results are unlikely to change substantially once the whole dataset reaches a mature follow-up (see supplemental material, reference<sup>17</sup>). In October 2015, the FDA approved TTFields for use in newly diagnosed GBM patients.

### Toxicity, Support, and Quality of Life with TTFields

Toxicity related to TTFields therapy consisted, by the nature of this treatment, mainly of local skin irritation. This is usually mild, self-limiting, easily manageable with local application of steroid-containing ointments, and may require an occasional treatment break for a few days. In the EF-11 trial, skin toxicity was reported in 16% of patients (grade 3 in only 2%). In the EF-14 trial for newly diagnosed GBM patients, where the treatment exposure was longer than that for recurrent disease,

grades 1 and 2 skin reactions were reported in 43% of patients. Severe (grade 3) reactions were again seen in only 2% of patients. Examples of allergic contact dermatitis, irritant contact dermatitis, folliculitis, and erosions are shown in → fig. 5.<sup>21</sup>

Importantly, when compared with TMZ maintenance treatment alone, the addition of TTFields did not result in any modification of the overall incidence, severity, and distribution of side effects in patients with newly diagnosed GBM. The incidence of seizures was identical in both treatment groups (7% in the TTFields group vs 8% in the control group). Some nonspecific adverse effects including nervous system disorders such as grade 1–2 headache (21% in the experimental group vs 14% in patients with TMZ alone), mild anxiety, confusion, insomnia, and headaches were reported more frequently in the patients treated with TTFields plus TMZ and occurred mainly at the time of therapy initiation.

Given the need for continuous and long-term use of the TTFields device, the quality of life of patients has been a concern. In the EF-11 trial, there were no differences in global health and social functioning between patients treated with TTFields or chemotherapy. In fact, cognitive and emotional functioning was higher in the TTFields group than in the chemotherapy group.<sup>16</sup> In the EF-14 trial, preliminary quality of life

**Fig. 5.** Skin toxicities observed under tumor treating fields (TTFields). Some mild-moderate (grade 1–2) skin reaction is observed in up to half of patients (in EF-14 trial reported in 43%, grade 3 in 2%); however, it is usually self-limiting and resolves by removing the electrodes for a few days and applying local steroid-containing ointments. The images represent a few examples of skin reactions. (A) allergic contact dermatitis (B) irritant contact dermatitis (C) folliculitis (D), erosions [Reproduced from ref. 21].

data showed identical scores at baseline and at 12 months for patients in the treatment and control groups at the levels of cognitive, emotional, physical, and social functioning.<sup>22</sup> Moreover, the global health status showed an improvement at 3 and 6 months in comparison with baseline for patients treated with TTFields and TMZ, whereas patients in the control group showed a decrease in global health status over the same time period.

## Discussion

More than a decade ago, *in vitro* and *in vivo* experiments in tumor cell lines and in mouse, rat, and rabbit tumor models have demonstrated antitumor activity of low-intensity, intermediate-frequency alternating electric fields. Dividing cells are arrested in metaphase and anaphase, assembly and function of the mitotic spindle are perturbed, and cells ultimately undergo apoptosis. However, in order to translate these findings into a clinically useful treatment, certain conditions must be met: (1) TTFields need to be delivered in a continuous manner to achieve the expected cytotoxic effect; (2) TTFields can only be applied to certain areas of the body, and this (3) requires the possibility to affix transducer array to the skin of the patient over the area of the tumor. As GBM is a disease that remains confined to the CNS and the scalp offers an easy application site for long-term use of transducer arrays, it appeared to be the ideal candidate to serve as a proof of concept demonstration of TTFields.

Two pivotal randomized trials have been reported to date. In recurrent disease, the trial has not demonstrated

improved outcome compared best physicians' choice chemotherapy. However, TTFields when administered as part of the initial treatment in newly diagnosed patients showed a consistent prolongation of both PFS and OS (hazard ratio for death HR: 0.74 (95% CI, 0.56–0.98)). Giving TTFields early in the disease course allows for prolonged exposure, and the *in vitro* observed synergy with TMZ may further enhance its efficacy. The median treatment duration in recurrent disease was only 2.3 months compared with 9 months in newly diagnosed GBM. Still, TTFields alone in recurrent disease have shown objective responses in 14% of patients, consistent or even numerically higher than that observed in other trials using alkylating agent chemotherapy with lomustine<sup>23,24</sup> or TMZ.<sup>25</sup> In the PriDE dataset reflecting routine clinical use of the device, patients who received TTFields at first recurrence were treated for a median of 6.2 months and had a median survival of 20 months, comparing favorably with recent trial results investigating other novel agents. However, a strong selection bias and inclusion of patients with pseudoprogression after initial TMZ chemoradiotherapy cannot be ruled out in this uncontrolled routine practice patient population.<sup>26</sup> The best results with this novel treatment modality have been achieved when TTFields were administered early in the disease course in combination with standard maintenance TMZ therapy,<sup>17</sup> similar to that shown 10 years ago when TMZ was added to standard radiotherapy.

It may be scientifically regrettable that the trial had to be open label and did not include a double-blinded control group. However, a sham device would neither be practically feasible (some heating of the electrodes is inevitable; technically

savvy patients would rapidly figure out whether there is any current flowing), nor acceptable for patients, caregivers, and ethics committees given the perceived burden of shaving the scalp and replacing transducer arrays every 3 days. Whereas some placebo effect might be expected on subjective endpoints, such as quality of life or cognitive function, it is difficult to envision an effect on objective endpoints such as OS or PFS (especially when progression was determined by blinded central radiologists).<sup>27</sup> Requiring a placebo or sham device would also mean a paradigm shift in conducting clinical trials with survival endpoints in oncology. Sham radiation therapy would be required for RT trials, and a placebo control would only be feasible for agents that have rare and mild toxicities.

Indeed, patients receiving TTFields therapy received some additional assistance by the technical support team providing the TTFields device and arrays. However, this support was on average limited to 1 visit per month, and 1–2 extra visits or contacts at the initiation of treatment. Most patients became rapidly independent and self-proficient with the device; on average, there was a median of 1.12 visits per patient and month of treatment (range, 0.5–4 visits per month).

It is highly unlikely that this additional technical support would translate into a 3-month prolongation of median survival, which is in the range of the benefit seen with the introduction of TMZ.<sup>26</sup> In a contemporary randomized open-label non-placebo-controlled trial, patients in the experimental arm received twice weekly i.v. administration of cilengitide. Still, this did not translate into any benefit in outcome (hazard ratio for death: 1.02; 95% CI 0.81–1.29).<sup>28</sup>

It might have been possible that the control arm in EF-14 performed exceptionally poorly. We thus scrutinized the data and compared the performance of the control arms of contemporary trials. The patient characteristics of both the TTFields and control groups were comparable with other clinical trials for newly diagnosed GBM patients in respect to all known prognostic factors (distribution of age, performance status, extent of resection, *MGMT* status).

One important difference in the EF-14 trial compared with many other reports is that patients were randomized only after the end of chemoradiotherapy, and for most patients the first cycle of maintenance TMZ had already been started at time of randomization. This implies that all patients with early tumor progression during the concomitant radiation and TMZ part of the treatment were excluded from this trial. On the other hand, the 3.8 months from diagnosis to randomization will need to be added to survival times in order to have an estimate of the individual patients' effective outcome. The PFS of 4.0 months (from randomization) observed in the control group of the EF14 trial is numerically shorter (likely due to the independent imaging review and assessment of progression) but overall comparable to the observed PFS of 5.5 months observed in the RTOG 0525 trial,<sup>29</sup> a trial that also randomized patients only after completion of the concomitant radiochemotherapy part of treatment. Moreover, in both trials, the OS was identical at 16.6 months for the control groups. It is therefore unlikely that the benefit observed in the treatment group of the EF14 trial can be attributed to patient selection and a poor outcome of patients in the control arm.

For many experts in neuro-oncology who were not involved in the trial, the most important criticism to TTFields was the requirement for patients to wear a device and their presumed stigmatization. Having to shave the scalp is indeed a psychological barrier, although in oncology, for decades we have been using cytotoxic agents that are inducing complete hair loss of all body hair and not only the scalp. In our experience, patients and families rapidly adapt to wearing the device and are able to continue their regular activities including work and even sports. Preliminary analysis of the self-reported quality of life data from the EF14 trial showed identical scores for both groups at baseline and at 12 months for patients in the treatment and control group at the levels of cognitive, emotional, physical, and social functioning.<sup>22</sup> To reduce some of the burden of therapy, a second generation of the TTFields device with a reduction in size and weight by about 50% compared with the device used in the EF-11 and EF-14 devices has been developed.

## Conclusions & Future Perspectives

The results of the randomized phase III EF-14 trial provide level 1 evidence that alternating electric fields are able to positively impact tumor growth and significantly extend survival in GBM. As a logical consequence, TTFields were approved by the FDA for newly diagnosed GBM in October 2015. Nevertheless, numerous questions remain and need to be addressed, both within the EF-14 trial and in future studies; Notably, it will be essential to be able to (1) identify the patients most likely to respond to TTFields therapy, (2) further elucidate the mechanism of action of TTFields, (3) elucidate the mechanisms of resistance to and failure of TTFields therapy, and (4) elucidate the pattern and predictors of response.

In GBM we will need to integrate this novel treatment approach in the current standard of care, and ultimately novel clinical trials will also need to integrate TTFields (at least in the control arm). A pragmatic alternative is to stratify patients for the use of TTFields as part of their standard of care in both the standard and experimental arms.

TTFields is a locoregional treatment, and extending its use to other tumor types and metastatic disease is most promising in clinical situations where locoregional disease control is key for quality of life. The excellent compatibility between TTFields and various chemotherapeutic agents has already been demonstrated, not only in GBM patients in the EF-14 trial but also in lung cancer patients.<sup>30</sup> TTFields may also be synergistic with immune therapy approaches. Senovilla et al showed that cells that cannot undergo mitotic exit show hallmarks of immunogenic cell death where the immune system induces a strong response against the dying cells.<sup>31</sup>

The positive results of the EF-14 demonstrate that neuro-oncology can lead the way to innovation. The results of the EF-14 trial paves the way to investigate the role of alternating electrical fields in other oncologic situations amenable to locoregional treatment such as brain metastases, ovarian carcinoma, mesothelioma, or pancreatic tumors (→ table 2). These trials are currently ongoing. For instance, in pancreatic cancer, TTFields therapy, in addition to gemcitabine resulted in a median PFS of 8.3 months (CI, 3–10.3 mo) in a phase 2 study

# Post Hoc Analyses of Intention-to-Treat Population in Phase III Comparison of NovoTTF-100A™ System Versus Best Physician's Choice Chemotherapy

Andrew A. Kanner,<sup>a</sup> Eric T. Wong,<sup>b</sup> John L. Villano,<sup>c</sup> Zvi Ram<sup>a</sup>, on behalf of EF-11 Investigators

We performed a treatment-based analysis of data from the pivotal phase III trial of the NovoTTF-100A System™ versus best physician's choice (BPC) chemotherapy in patients with recurrent glioblastoma multiforme (GBM), with particular focus on efficacy in patients using NovoTTF Therapy as intended. Median overall survival (OS) was compared for recurrent GBM patients receiving at least one full cycle of treatment with NovoTTF-100A System or BPC chemotherapy (modified intention-to-treat [mITT] population) in the recently reported phase III trial. The relationship between NovoTTF-100A System compliance and OS was evaluated in the ITT population. Kaplan-Meier analyses examined treatment-related differences in OS for various patient subgroups. Median OS was significantly higher in patients receiving  $\geq 1$  course of NovoTTF Therapy versus BPC (7.7 v 5.9 months; hazard ratio, 0.69; 95% confidence interval [CI], 0.52–0.91;  $P = .0093$ ). Median OS was also significantly higher in patients receiving NovoTTF Therapy with a maximal monthly compliance rate  $\geq 75\%$  ( $\geq 18$  hours daily) versus those with a  $< 75\%$  compliance rate (7.7 v 4.5 months;  $P = .042$ ), and Kaplan-Meier analysis demonstrated a significant trend for improved median OS with higher compliance ( $P = .039$ ). Additional post hoc analysis showed significantly higher median OS with NovoTTF Therapy than with BPC for patients with prior low-grade glioma, tumor size  $\geq 18$  cm<sup>2</sup>, Karnofsky performance status  $\geq 80$ , and those who had previously failed bevacizumab therapy. When used as intended in mITT patients with recurrent GBM, NovoTTF Therapy provides an OS benefit compared with chemotherapy in patients with recurrent GBM. This contrasts with the equivalent efficacy reported previously based on analysis of all randomized ITT subjects, including many who did not receive a full cycle of treatment. Higher NovoTTF Therapy compliance corresponds with greater survival benefit in the present study.

**G**lioblastoma multiforme (GBM) is the most common type of primary malignant brain tumor and presents a major challenge to the neuro-oncology community.<sup>1</sup> The overall prognosis is poor with best standard care, with as few as 8%-20% of patients surviving 2 years following diagnosis<sup>2</sup> and less than 5% surviving beyond 5 years.<sup>1</sup> GBM is characterized by infiltrative growth and invariably recurs even with aggressive initial therapy.<sup>3,4</sup> For patients with recurrent GBM, treatment options are limited, and there is no clear standard of care.<sup>3,5</sup> In 2009, bevacizumab received accelerated US Food and Drug Administration (FDA) approval for recurrent GBM based on phase II trials showing good response rates and progression-free survival compared with historical controls.<sup>5-8</sup> However, about 40% to 60% of treated patients with recurrent GBM are unresponsive to bevacizumab, while others experience serious adverse events,<sup>3,5,9</sup> and all

initially responsive patients relapse.<sup>5</sup> Hence, there is a critical need for additional treatments for patients with recurrent GBM.

The NovoTTF-100A System (Novocure Ltd., Haifa, Israel) is a novel antimitotic cancer treatment for recurrent GBM. The NovoTTF-100A System consists of a portable device that delivers alternating low-intensity, intermediate-frequency, tumor-treating electric fields (TTFields) to the patients' brain via noninvasive transducer arrays attached to the scalp.<sup>10</sup> TTFields have been shown to inhibit the growth and induce the death of a wide range of tumor cells in vitro and in animal tumor models.<sup>11,12</sup> More specifically, by disrupting mitotic spindle formation during metaphase-to-anaphase transition and by causing dielectrophoretic movement of charged or polar molecules and organelles during anaphase and telophase, TTFields promote selective destruction of GBM (or other rapidly dividing) cells via mitotic arrest and apoptosis.<sup>13,14</sup> Preclinical studies also suggest that combining TTFields with chemotherapy may enhance chemotherapeutic efficacy without increasing toxicity.<sup>15,16</sup> NovoTTF Therapy approval was based on pivotal phase III trial results.<sup>17</sup> In this trial, NovoTTF Therapy demonstrated equivalent overall survival (OS) as compared to best physician's choice chemotherapy in patients with recurrent GBM, with significantly fewer serious adverse events and significantly better quality of life.<sup>17</sup>

Given the mechanism of action of TTFields—which, unlike drug therapy, does not include a half-life and applies only during use—we hypothesized superior efficacy would be observed with the NovoTTF-100A System in an analysis of the phase III data that focused on the “as-treated” or modified intention-to-treat (mITT) population rather than on the ITT population examined in the original report. The mITT population included all NovoTTF Therapy patients receiving at least one predefined treatment course (28 days), and all chemotherapy patients receiving at least one course of chemotherapy. To evaluate this hypothesis, we performed a post hoc analysis of the pivotal phase III trial data to investigate the impact of at least one full course of NovoTTF Therapy or chemotherapy on OS in patients. We also examined the correlation between NovoTTF Therapy compliance and OS.

In addition, we performed a number of post hoc analyses to compare OS rates in subgroups of patients in the ITT population who were treated with NovoTTF Therapy or chemotherapy. Of particular interest was the subgroup consisting of patients who had previously failed bevacizumab therapy. More generally, there have been recent reports of very extended and ongoing survival of a subset of patients treated with NovoTTF Therapy,<sup>18,19</sup> and the

post hoc analyses here represent an attempt to identify patient- or disease-related characteristics predictive of response to NovoTTF Therapy. A recent post hoc study by Wong and coworkers<sup>20</sup> of the pivotal phase III trial data identified prior low-grade histology and lower cumulative dexamethasone dose as important factors distinguishing NovoTTF Therapy responders from nonresponders among recurrent GBM patients. However, these variables did not distinguish response to chemotherapy, though the overall number of patients in this analysis was low.

## MATERIALS AND METHODS

### Patient Selection and Study Design

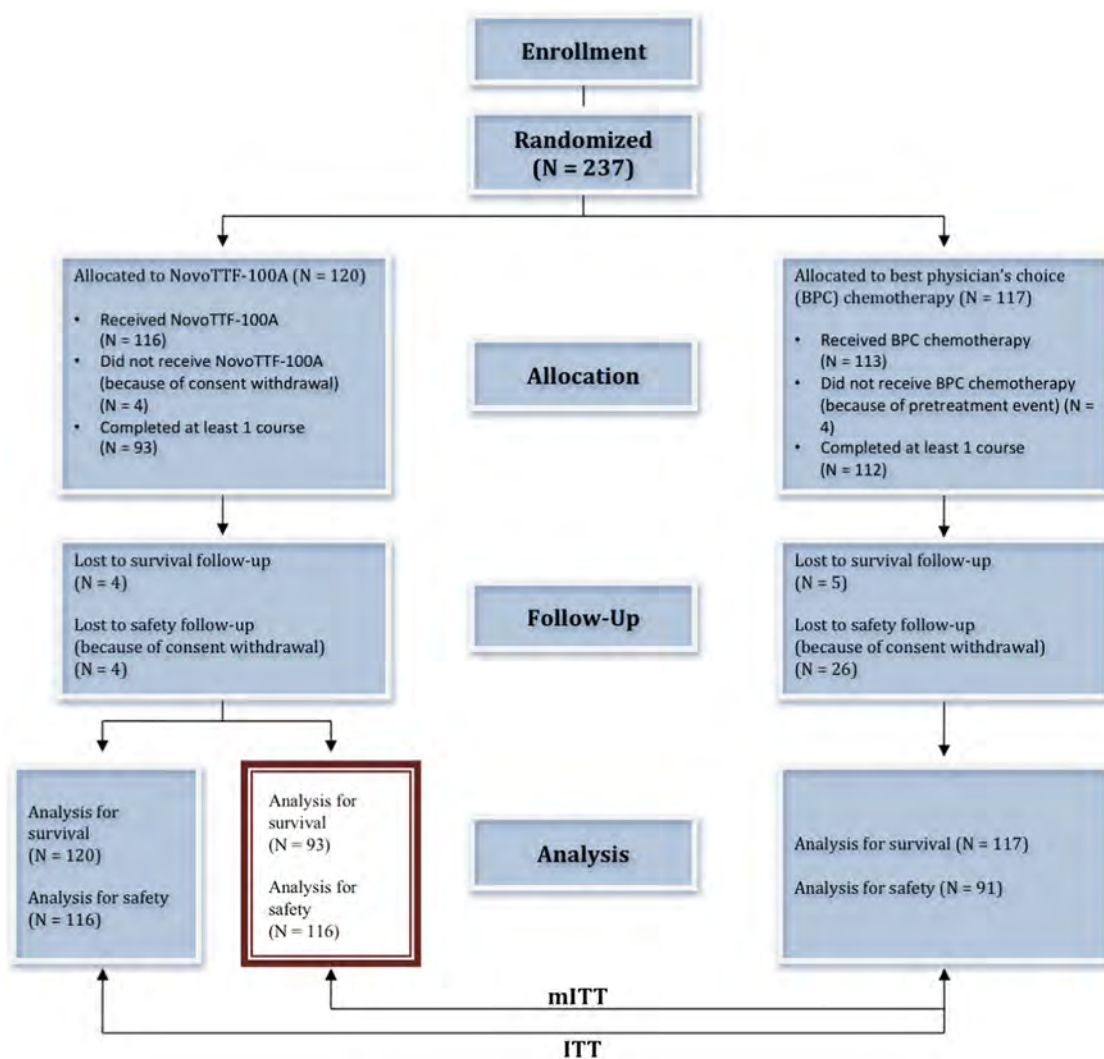

General details of the pivotal phase III trial of the NovoTTF-100A System in recurrent GBM have previously been reported.<sup>17</sup> A CONSORT (Consolidated Standards of Reporting Trials) diagram of the study appears as Figure 1,<sup>20</sup> and includes a breakdown of the respective numbers of patients in the ITT and mITT populations for the survival analysis.

Briefly, between September 2006 and May 2009, adult patients with histologically confirmed and prior treated GBM and radiologically confirmed disease recurrence or progression were randomized in a 1:1 ratio to receive either NovoTTF Therapy (monotherapy) or chemotherapy. Prior therapy had to include radiotherapy, with or without concomitant temozolomide. There was no limit on number or type of prior therapies or recurrences. Patients with an implanted electronic medical device or with an supratentorial tumor location were excluded from enrollment because of a physical limitation: the majority of the electric fields delivered from the transducer arrays on the scalp distributed to the supratentorial part of the brain. For patients assigned to the NovoTTF Therapy group, treatment was self-administered and continuous while they maintained normal daily activity. Patients assigned to the chemotherapy group received a chemotherapy regimen of the local investigator's choice, based on local practice and prior treatment exposure.<sup>17</sup> One cycle of NovoTTF-100A System treatment consisted of continuous treatment for 28 days or 4 weeks, while one cycle of chemotherapy consisted of delivery of the drug until recovery of blood counts or side effects, which usually required 4 to 6 weeks.

### Statistical Analysis

The principal endpoint for the subgroup analyses was OS, computed from the day of randomization until event (death) or censored at the last follow-up according to the Kaplan-Meier method. All survival comparisons between groups were performed using

**Figure 1.** CONSORT (Consolidated Standards of Reporting Trials) flow diagram and modified intention-to-treat (mITT) and ITT populations.

a two-sided log-rank (Mantel-Cox) test with  $\alpha$  of 0.05. Unless otherwise stated, all analyses were performed using the ITT population (all randomized patients regardless of whether they received any treatment). A Cox proportional hazards model (CPHM) was initially used to identify subgroups warranting further evaluation in post hoc analyses. The CPHM used a direct model including all baseline patient and disease characteristics simultaneously. Only characteristics that independently met a  $p$  value of 0.15 or below were considered significant. Based on the results of the CPHM, treatment-related effects on OS were analyzed for the following specific patient subgroups: age ( $\leq 60$  years or  $> 60$  years), Karnofsky performance status (KPS;  $\geq 80$  or  $< 80$ ), surgery status (biopsy only or any resective surgery), GBM type (secondary [prior low-grade glioma] or primary), tumor size ( $\geq 18$  cm<sup>2</sup> or  $< 18$  cm<sup>2</sup>), and bevacizumab failure versus non-bevacizumab failure (prior to enrollment). Treatment-related effects on

OS were also analyzed for reoperation status (yes or no) and maximal compliance ( $\geq 75\%$  or  $< 75\%$  of treatment time [hours/day use]).

Log-rank OS comparisons of the ITT population also were performed for NovoTTF Therapy versus bevacizumab and for NovoTTF Therapy versus chemotherapy (excluding bevacizumab). Differences in OS between NovoTTF Therapy and chemotherapy (including bevacizumab) also were analyzed for the mITT population. The mITT population included all NovoTTF Therapy patients who received at least 1 course of treatment (28 days), and all patients randomized to the chemotherapy group who received at least one course of any chemotherapy protocol, including bevacizumab alone or in combination with cytotoxic chemotherapy.

The relationship between NovoTTF Therapy compliance (calculated as percentage use per day) and mean OS was compared using the Spearman rank correlation coefficient for 40%–59%, 60%–79%, and

80%–100% compliance. The portable device has an internal log file that allows the calculation of patient compliance. Treatment time evaluation was calculated from the first day of a patient's treatment until the last. When a patient did not complete a full 28-day course, the percentage reported was the total number of days treatment was received. This percentage reflected patient compliance with treatment and represented the average daily "dose" of TTFields received. Trend analysis of the relationship between compliance and OS was examined using Kaplan-Meier curves for compliance subgroups and the log-rank test for trend.

## RESULTS

### Patients

The ITT and mITT populations for the NovoTTF Therapy cohort consisted of 120 and 93 patients, respectively, while the ITT and mITT populations of the chemotherapy cohort each contained 117 patients. Baseline characteristics of the ITT population were previously reported.<sup>17</sup> Of note, patient characteristics were balanced for the two treatment groups. Eight percent of patients in both the NovoTTF Therapy group and the active chemotherapy group had a history of prior lower-grade glioma; 21% of NovoTTF Therapy patients and 15% of active chemotherapy patients had a biopsy only; >80% of patients failed two or more prior lines of chemotherapy; and 19% of NovoTTF Therapy patients and 18% of chemotherapy patients failed prior bevacizumab therapy.<sup>17</sup>

### As-Treated (mITT) Analysis of Median OS

Median OS in patients who received at least one course of NovoTTF Therapy was significantly longer

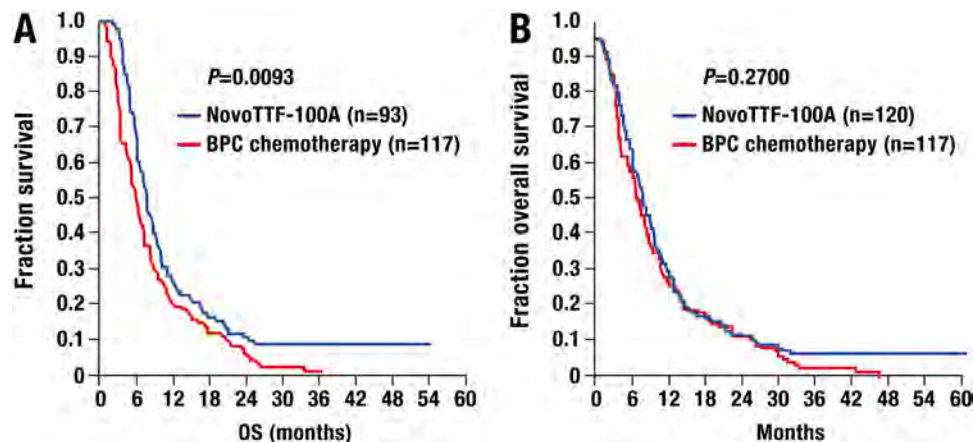

than in patients who received at least one course of any active chemotherapy, including patients who received bevacizumab off-label instead of entering the study (7.8 v 6.0 months, respectively; hazard ratio [HR], 0.69; 95% CI, 0.52–0.92;  $\chi^2 P = .0093$ ). The Kaplan-Meier survival curves are shown in Figure 2.

### Compliance

Ninety-two (77%) of the patients in the ITT population received NovoTTF Therapy  $\geq 75\%$  of the time (median compliance, 86%; range, 41%–98%). Median OS for NovoTTF Therapy patients with a monthly compliance rate  $\geq 75\%$  ( $n = 92$ ) was significantly longer than for patients who received treatment  $< 75\%$  ( $n = 28$ ) of the time, 7.7 v 4.5 months, respectively (log-rank  $P = 0.042$ ). When the NovoTTF Therapy cohort was further subdivided into three groups according to extent of compliance (40%–59%, 60%–79%, or 80%–100% compliance for each 24-hour period), there were 10 (8%), 33 (28%), and 77 (64%) patients in each group, respectively. A Spearman rank correlation test indicated a positive correlation between treatment compliance and mean OS (correlation coefficient, 0.175; one-sided  $P = .030$ ) (Figure 3A). Kaplan-Meier analysis demonstrated a significant trend for improved median OS with higher compliance: median OS of 5.8, 6.0, and 7.7 months for  $< 60\%$  ( $n = 10$ ), 60%–79% ( $n = 33$ ), and 80%–99% ( $n = 77$ ) compliance, respectively (log-rank test for trend,  $\chi^2 P = .039$ ) (Figure 3B).

### Subgroup Analyses (ITT population)

Median OS was significantly longer in the NovoTTF Therapy group than in the chemotherapy group for patients who had previously failed bevacizumab, had a prior low-grade glioma, had larger baseline tumor size, and those with higher KPS

**Figure 2.** Kaplan-Meier overall survival for modified intention-to-treat (mITT) (A) and intention-to-treat (ITT) (B) populations with recurrent glioblastoma multiforme treated with NovoTTF Therapy or BPC (best physician's choice) chemotherapy in the phase III trial.

**Figure 3.** (A) Spearman rank correlation between NovoTTF Therapy compliance and mean overall survival (OS) showed a correlation coefficient of 0.175 (1-sided  $P = .030$ ). (B) Kaplan-Meier OS curves stratified according to compliance. There was a trend for longer median OS with better compliance, with median OS of 5.8 months for <60% compliance ( $n = 10$ ), 6.0 months for 60% to 79% compliance ( $n = 33$ ), and 7.7 months for 80% to 99% compliance ( $n = 77$ ) (log-rank test for trend,  $\chi^2 P = .039$ ).

(Table 1). First, among patients who had previously failed bevacizumab prior to enrollment, median OS of those treated with NovoTTF Therapy was 6.0 months ( $n = 23$ ) versus 3.3 months ( $n = 21$ ) for those treated with chemotherapy (HR, 0.43; 95% CI, 0.22–0.85;  $\chi^2 P = .016$ ). Second, for patients who had prior low-grade glioma histology, those treated with NovoTTF Therapy had a median OS of 25.3 months ( $n = 12$ ) versus 7.7 months ( $n = 9$ ) for those who received chemotherapy (HR, 0.31; 95% CI, 0.09–0.99;  $\chi^2 P = .049$ ). Third, for patients who had a baseline tumor size of  $\geq 18 \text{ cm}^2$ , NovoTTF Therapy treatment was associated with a median OS of 5.6 months ( $n = 39$ ) versus 3.3 months ( $n = 41$ ) for those offered chemotherapy (HR, 0.53; 95% CI, 0.32–0.85;  $\chi^2 P = .009$ ). Last, for patients with baseline KPS  $\geq 80$ , subjects treated with NovoTTF Therapy had a median OS of 7.9 months ( $n = 83$ ) versus 6.1 months ( $n = 77$ ) for those treated with chemotherapy (HR, 0.71; 95% CI, 0.51–0.99;  $\chi^2 P = .045$ ) (Figure 4).

Because we observed a significant difference in treatment efficacy between the two trial cohorts who had failed bevacizumab prior to enrollment, we asked whether there is also a difference in efficacy between NovoTTF Therapy and chemotherapy. Indeed, median OS was also significantly longer for patients who received NovoTTF Therapy than for those who received bevacizumab for recurrent GBM in the trial control group, 6.6 months ( $n = 120$ ) versus 4.9 months ( $n = 36$ ), respectively (HR, 0.64; 95% CI, 0.41–0.99;  $\chi^2 P = .045$ ), but not for those who received non-bevacizumab chemotherapy, 6.6 months ( $n = 120$ ) versus 6.6 months ( $n = 84$ ) (HR, 0.92; 95% CI, 0.68–1.24;  $\chi^2 P = .586$ ) (Figure 5). Table 2 provides the baseline characteristics of patients in the NovoTTF Therapy and bevacizumab groups.

Median OS did not significantly differ between NovoTTF Therapy and chemotherapy in the following subgroups (Table 1): non-bevacizumab failures (6.7 and 7.2 months, respectively; HR, 0.95; 95% CI, 0.70–1.27;  $\chi^2 P = .714$ ); patients without prior history of low-grade glioma (6.6 and 5.8 months, respectively; HR, 0.95; 95% CI, 0.72–1.26;  $\chi^2 P = .744$ ); tumor size  $< 18 \text{ cm}^2$  (7.3 and 8.3 months, respectively; HR, 0.99; 95% CI, 0.71–1.37;  $\chi^2 P = .941$ ); KPS  $< 80$  (4.8 and 5.4 months, respectively; HR, 1.26; 95% CI, 0.79–2.02;  $\chi^2 P = .338$ ); age  $\leq 60$  years (7.4 and 6.2 months, respectively; HR, 0.74; 95% CI, 0.54–1.02;  $\chi^2 P = .063$ ); age  $> 60$  years (4.8 and 5.7 months, respectively; HR, 1.31; 95% CI, 0.78–2.19;  $\chi^2 P = .309$ ); patients who received any surgery (6.2 and 6.0 months, respectively; HR, 0.99; 95% CI, 0.74–1.33;  $\chi^2 P = .959$ ); and patients who had biopsy only (7.9 and 5.8 months, respectively; HR, 0.54; 95% CI, 0.27–1.09;  $\chi^2 P = .085$ ). Median OS was also similar in both NovoTTF Therapy and chemotherapy patients who underwent reoperation before randomization (7.4 and 7.4 months, respectively) and in non-reoperated patients (6.3 and 5.3 months respectively).

## DISCUSSION

This analysis demonstrates that NovoTTF Therapy, when used as intended in the mITT population who participated in the phase III trial, is associated with significantly longer median OS than is BPC chemotherapy in patients with recurrent GBM. We found that NovoTTF Therapy was associated with nearly 2 months longer survival (7.8 v 6.0 months) and a roughly 30% reduction in risk of death (HR, 0.69; 95% CI, 0.52–0.92;  $\chi^2 P = .012$ ) when compared to patients treated with BPC chemotherapy.

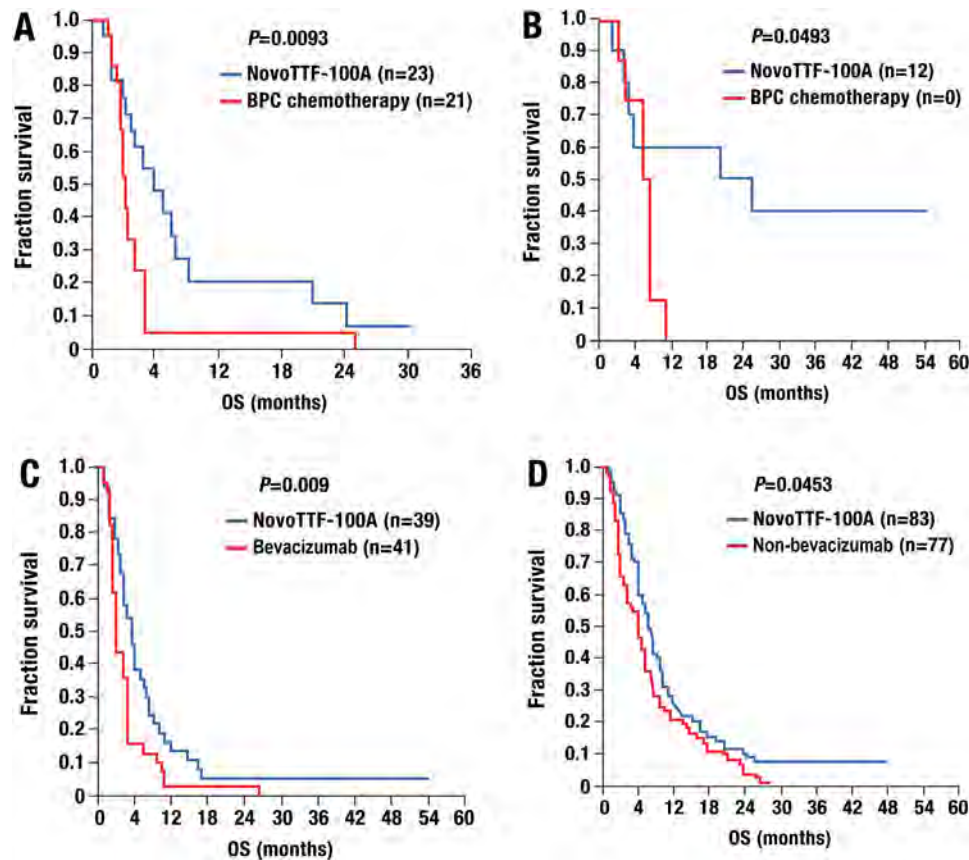

**Table 1.** Subgroup Analyses Showing Overall Survival for NovoTTF Therapy Versus BPC Chemotherapy Patients in the Intention-To-Treat Population

	NovoTTF Therapy	Chemotherapy	Hazard Ratio (95% CI)	Log-Rank P
<b>Prior bevacizumab failure</b>				
Patients, n	23	21	—	—

Median OS, mo	6.2	6.0	0.99 (0.74-1.33)	.9590

These data are distinct from the equivalent OS seen in the ITT population.<sup>17</sup> However, the ITT population included all randomized patients, many of whom did not receive a full cycle of NovoTTF Therapy and hence might not have been the best population for testing treatment efficacy against chemotherapy. This is because the anti-tumor effect from alternating electric fields requires continuous treatment and disappears when stopped, while the

biological effects of chemotherapy may persist for 4 to 6 weeks after dosing. The requirement of continuous application of NovoTTF Therapy was tested in prior models of GBM, which suggested that a minimum of four weeks of continuous treatment is required for tumor stasis or shrinkage (see Vymazal et al in this supplement). Consistent with the model data, we included in the mITT analysis patients who received at least one

**Figure 4.** Kaplan-Meier overall survival (OS) curves stratified according to patient subgroups in the intention-to-treat (ITT) population with (A) prior bevacizumab failure, (B) prior low-grade glioma, (C) tumor size  $\geq 18$  cm<sup>2</sup>, and (D) Karnofsky performance status  $\geq 80$ . BPC = best physician's choice.

continuous 28-day cycle of NovoTTF Therapy and compared them to patients who received chemotherapy, which varied depending on the specific regimen but always consisted of one treatment cycle, as chemotherapies were administered in an intermittent fashion. Arguably, the mITT analysis

provided a more accurate comparison of the two cohorts because they received similar treatment amounts as intended for the trial. Therefore, while the reported results for the ITT population established similar efficacy between NovoTTF Therapy and chemotherapy in recurrent glioblastoma, the

**Figure 5.** Overall comparison of Kaplan-Meier overall survival (OS) curves for intention-to-treat (ITT) population with recurrent glioblastoma multiforme treated with NovoTTF Therapy (n = 120) versus (A) bevacizumab (n = 36) or (B) non-bevacizumab (n = 81) chemotherapy.

**Table 2.** Baseline Characteristics of Patients in the NovoTTF Therapy and Bevacizumab-Treated Subgroup, Respectively (Intention-to-Treat Population)

Characteristic	NovoTTF Therapy (n = 120)	Bevacizumab (n = 36)

Median (range) dexamethasone dose per day, mg	4.7 (0-38)	4.7 (0-21)

present results from the mITT population suggest NovoTTF Therapy is associated with a better survival benefit when used as intended.

It should be noted that our mITT comparison is limited by the post hoc nature of the analysis, as well as the major difference between the mechanisms of action of NovoTTF Therapy and of the chemotherapies used in the active control arm of the study. Nevertheless, this post hoc analysis allowed us to estimate the magnitude of the difference in OS between the mITT and ITT cohorts treated with NovoTTF Therapy. This is important because future trials of this device in recurrent GBM will need to take into account the effect of early discontinuation on efficacy outcome by having a larger sample size or a lead-in phase to test patients for device compliance in the first 28 days. Furthermore, removing patients who received <28 days of NovoTTF Therapy may have inadvertently biased the mITT analysis in favor of the device because those who did not complete a full cycle of treatment may have stopped because of clinical deterioration. Patients in the control arm who deteriorated at a similar time point may have already completed a full treatment cycle of their assigned chemotherapy. Therefore, the true survival difference between these two groups may lie between the outcomes of the mITT and ITT analyses.

There appears to be a relationship between NovoTTF Therapy compliance and OS. Patients who had an average monthly treatment compliance of more than 75%, which is 18 hours per day or more, had a median OS of 7.7 months, versus 4.5 months for those patients who were compliant <75% of the time. Median OS also appeared to increase in a stepwise fashion with increasing compliance, from 5.8 months with low compliance (<60%) to 6.0 months with medium compliance

(60%–79%) and 7.7 months with high compliance (80%–99%) (log-rank test for trend,  $P = .038$ ). The progressively higher variability from the low- to high-compliance groups may account for the lower Spearman correlation coefficient, but the differences in OS between these compliance groups are still significant. Consistent with the preclinical data, NovoTTF Therapy exerts its antimitotic effect during the times it is applied, and, unlike chemotherapies, it does not have a half-life associated with its mechanism of action. Therefore, our data support the recommended usage for this device:  $\geq 4$  weeks at an average of  $\geq 18$  hours a day (75% of each 24-hour period) for the total number of days.<sup>21</sup>

It can be argued that patients who were more compliant with NovoTTF Therapy were in a better clinical state, which may in turn independently predict longer survival. However, entry into the trial required a KPS of 70 or greater, and this level of KPS would allow the patient to have independent function and management of the device with a caretaker. Furthermore, Vymazal and Wong (in this supplement) also demonstrated a relationship between compliance and radiologic response, suggesting that the extent of compliance may be viewed as the treatment dose exerted onto the tumor. Together, compliance is probably an independent predictor of longer OS, but future prospective testing in a clinical trial is necessary to confirm this observation.

The present study also included post hoc analyses of various patient subpopulations from the phase III clinical trial. The intent here was to identify patient subgroups in the ITT population who might be more responsive to NovoTTF Therapy than active chemotherapy. In future studies, these subgroups can be more rigorously examined in a prespecified fashion, and with sufficient power, to prospectively detect treatment-related differences. Recent reports of

recurrent GBM patients alive 6 years or more after beginning NovoTTF Therapy highlight the need to better identify the clinical characteristics of patients predictive of a robust response to NovoTTF therapy.<sup>18,19</sup> Furthermore, another recent post hoc analysis of the phase III data found higher proportions of secondary GBM (prior low-grade histology) and low dexamethasone usage in recurrent GBM patients who responded to NovoTTF Therapy than in those who did not.<sup>20</sup> The authors suggested that these as well as other genetic/epigenetic factors might determine response to Novo TTF Therapy. The present study identified a number of variables that need to be confirmed and included in future clinical trials. These variables include prior low-grade glioma (or secondary recurrent GBM), tumor size  $\geq 18$  cm<sup>2</sup>, KPS  $\geq 80$ , and patients who had previously failed bevacizumab therapy. Compared to the rest of the cohort, patients with prior low-grade gliomas, tumor size  $\geq 18$  cm<sup>2</sup>, and KPS  $\geq 80$  may have tumors with slower growth or a location farther away from neurologically functional areas of the brain, allowing sufficient time for NovoTTF Therapy to exert its anti-tumor effect. Those who have failed prior bevacizumab therapy may already have an altered immunologic milieu within the tumor microenvironment, facilitating immunogenic cell death that was induced by NovoTTF Therapy.<sup>22,23</sup> Because our findings are based on univariate analyses of multiple, originally unspecified subgroups, they should be viewed with caution, and as hypothesis-generating rather than definitive conclusions. The limitations of subgroup analyses—especially when multiple parameters are examined post hoc, without a prespecified condition or sufficient power to detect differences between groups—include an increased risk for type I and type 2 errors.<sup>24–26</sup>

Although bevacizumab has been approved as treatment for recurrent GBM, some patients with recurrent GBM are initially unresponsive to bevacizumab, while the rest of initially responsive patients eventually become refractory over time.<sup>3,5</sup> Given this observation, it is worth noting that our analysis of patients who had failed bevacizumab therapy demonstrated a significantly longer OS in patients treated with NovoTTF Therapy than in patients who received chemotherapy, 6.0 months ( $n = 23$ ) and 3.3 months ( $n = 21$ ), respectively. Another analysis, comparing the entire NovoTTF Therapy cohort with patients treated with bevacizumab only in the active control group, showed that OS was significantly longer with NovoTTF Therapy compared to bevacizumab, 6.6 months ( $n = 120$ ) and 4.9 months ( $n = 36$ ), respectively ( $P = .045$ ). It is worth noting that these results are the only published randomized results on the efficacy of bevacizumab compared

head-to-head with another active treatment. Further substantiation of these findings is warranted in a prospectively designed trial.

In summary, treatment options for recurrent GBM are limited, and there is no consensus as to best therapy at time of recurrence.<sup>3,5</sup> The NovoTTF-100A System was recently approved for recurrent GBM based on phase III trial results that showed equivalent efficacy with better toxicity and quality-of-life profiles compared with chemotherapy.<sup>17</sup> Results from the present study suggest that, when used as intended, NovoTTF Therapy provides efficacy superior to that of chemotherapy in a heterogeneous population of patients with recurrent GBM. Post hoc analyses identified subgroups of patients who may be particularly good candidates for NovoTTF Therapy, pending further confirmatory studies.

# Characterization and Management of Dermatologic Adverse Events With the NovoTTF-100A System, a Novel Anti-mitotic Electric Field Device for the Treatment of Recurrent Glioblastoma

Mario E. Lacouture,<sup>a</sup> Mary Elizabeth Davis,<sup>a</sup> Grace Elzinga,<sup>b</sup> Nicholas Butowski,<sup>c</sup> David Tran,<sup>d</sup> John L. Villano,<sup>e</sup> Lucianna DiMeglio,<sup>f</sup> Angela M. Davies,<sup>f</sup> and Eric T. Wong<sup>b</sup>

The NovoTTF-100A System (NovoTTF™ Therapy, Novocure Inc.) is a device that delivers alternating electric fields (TTFields) to tumor cells and interferes with mitosis. It is approved for use as monotherapy for the treatment of recurrent glioblastoma (rGB). TTFields are delivered through insulated transducer arrays applied onto the shaved scalp and connected to a battery-operated field generator. The occurrence of dermatologic adverse events (dAEs) is primarily due to the continuous contact between the array-related components and the scalp for periods of 3–4 days (together with other risk factors). These dAEs may include allergic and irritant dermatitis, mechanical lesions, ulcers, and skin infection. The incidence of dAEs in the phase III trial (n = 116) was 16% (2% grade 2, 0% grade 3/4); the post-marketing surveillance program (n = 570) revealed 156 (21.8%) dAEs with some patients reporting more than one event. Prophylactic strategies for dAEs include proper shaving and cleansing of the scalp and array relocation. Treatment-based strategies are AE-specific and include topical or oral antibiotics, topical corticosteroids, and isolation of affected skin areas from adhesives and pressure. The addition of skin care strategies to the NovoTTF-100A System use will maximize adherence to therapy while maintaining quality of life, all of which contribute to the therapeutic benefit of NovoTTF Therapy in rGB. *Semin Oncol* 41:S1-S14 © 2014 Elsevier Inc. ## INTRODUCTION AND BACKGROUND

### Glioblastoma

**M**alignant gliomas are a group of primary brain tumors that are heterogeneous, highly invasive, and aggressive.<sup>1,2</sup> Glioblastoma (GB) is

classified by the World Health Organization as a grade IV tumor with a median survival of only 15 months and a 5-year survival rate of less than 10%.<sup>3–6</sup> Despite advances in imaging techniques and multimodal treatment approaches, the overall prognosis of patients with GB is still poor.<sup>7</sup> In patients with

recurrent glioblastoma (rGB), response rates to systemic therapies are typically less than 10%, and the progression-free survival (PFS) at 6 and 12 months are 15% and 6%, respectively.<sup>8</sup> The median overall survival (OS) of these patients with salvage chemotherapy is 5.8 months with a 1-year survival rate of just 21%.<sup>8</sup> rGB patients who are surgical candidates have a median OS of only 4.6 months if left untreated.<sup>9</sup> Furthermore, although treatment with the vascular endothelial growth factor (VEGF) inhibitor, bevacizumab, results in a high radiographic response rate and prolonged PFS, there are no randomized data that demonstrate an increase in OS.<sup>10,11</sup> In fact, recent data have shown that in newly diagnosed GB patients, bevacizumab does not increase OS. Thus, there is a clear need for new and innovative approaches for the treatment of rGB.

### The NovoTTF-100A System

The NovoTTF-100A System (Novocure Inc., Portsmouth, NH) is a novel anti-mitotic device that delivers alternating electric fields (tumor-treating fields, TTFields), and is approved by the US Food and Drug Administration (FDA) and has a European Conformity (CE) mark in Europe for use as monotherapy for the treatment of rGB.<sup>12</sup> The basis of the approvals was a phase III study (EF-11) comparing NovoTTF Therapy to active standard chemotherapy in rGB patients.<sup>13</sup> The NovoTTF-100A System has been commercially available by prescription since 2011 in the United States.

The NovoTTF-100A System consists of four transducer arrays, a connector cable, a field-generating device, and a power source (battery or electrical outlet). Treatment parameters are preset (200 kHz and a minimal field intensity of 0.7 V/cm in the brain); thus, there are no electrical adjustments made by the patient or healthcare provider. TTFields are delivered through non-invasive insulated transducer arrays that are applied to the shaved scalp (Figure 1). The location of the arrays on the scalp is calculated using a simulation software (NovoTAL™, Novocure Inc.) that optimizes the field intensity within a patient's tumor based on head size and tumor location.

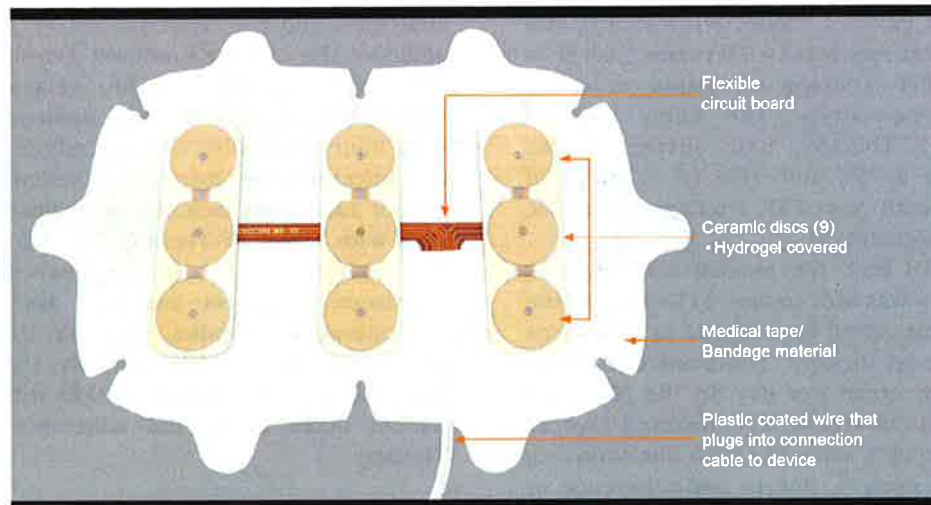

Transducer arrays are supplied to patients in individual sterile packages to minimize the risk of infection, although the application of the arrays to the scalp is not a sterile procedure. The arrays are composed of insulated ceramic discs (nine per array). The ceramic discs (with a high dielectric constant) are biocompatible and are soldered to a flexible circuit board (Figure 2). The ceramic discs do not come into direct contact with the skin as they are separated from the skin by a layer of conductive hydrogel (similar to that found on electrocardiogram

**Figure 1.** The NovoTTF-100A System. (A) NovoTTF-100A System with battery-operated field-generating device, connected transducer array (patient wears 4 arrays), and included backpack for portability. (B) The NovoTTF-100A System as worn during therapy.

pads). There is no direct electron transfer to the skin; ion concentration changes in cells do not occur, nor does electrolysis.<sup>14</sup> The ceramic discs, hydrogel, and circuitry are all attached to a hypoallergenic medical adhesive bandage to keep the arrays in place on the scalp and in continuous direct contact with the skin. A single plastic-coated wire

**Figure 2.** The NovoTTF-100A System Transducer Array.

from each array then plugs into the connection cable, which is attached to the field-generating portion of the device. Although patients have described a "warm sensation" during normal operation of the device, each array has eight temperature sensors (thermistors) that continuously monitor temperature. If the array temperature exceeds 41°C (105.8°F), which is below the threshold for a thermal skin burn,<sup>15</sup> the device will shut off and sound an alarm. The NovoTTF-100A System meets all FDA medical electrical equipment and biocompatibility standards.<sup>16</sup>

NovoTTF-100A Therapy is administered by affixing two pairs of orthogonally positioned transducer arrays to the shaved scalp. Adequate shaving of the scalp is required for optimum array-to-skin contact. The arrays are worn continuously for 3–4 days before removal for hygienic care of the scalp, re-shaving of hair, and reapplication with new sets of arrays.

### Mechanism of Action of the NovoTTF-100A System

While electric fields (at differing frequencies and intensities) have been used in medicine for many decades, it is only within the past decade that the biological effect of alternating electric fields at intermediate frequencies (100–300 kHz), and low intensity (1–3 V/cm), has been realized. Evaluation of these intermediate-frequency, alternating electric fields in multiple cancer cell lines has demonstrated an anti-mitotic effect that is both frequency-specific and intensity-specific in cancer cells, with no effect on non-mitotically active cells.<sup>14,17</sup> TTFs interfere with cancer cell division during three phases of mitosis: (1) metaphase, with inhibition of microtubule spindle assembly; (2) anaphase, with cytoplasmic blebbing and asymmetric chromosomal segregation;

and (3) telophase, with a dielectrophoretic effect, resulting in an inability of the organelles and macromolecules to segregate within the daughter cells due to the formation of a nonuniform field gradient.<sup>18–21</sup> TTFs do not cause cell membrane depolarization and thus do not stimulate nerves or muscles, nor do they cause thermal heating of tissues.<sup>22</sup> The current FDA-approved frequency and intensity settings for the NovoTTF-100A System are optimized for the treatment of rGB.

### Pivotal Phase III Study (EF-11)

A phase III randomized trial (EF-11) was conducted based on encouraging evidence of TTF activity in glioma animal models and subsequent pilot data in patients with newly diagnosed and recurrent glioblastoma demonstrating safety, feasibility, and promising efficacy.<sup>13,14</sup> This trial compared NovoTTF Therapy to active chemotherapy (based on physicians choice) in patients with rGB.<sup>13</sup> Patient characteristics were well balanced between the treatment arms of the trial, median age was 54 years, 19% of patients had previously been treated with bevacizumab, and 90% were at their second or later recurrence. Patients were randomized to NovoTTF Therapy alone (n = 120) or chemotherapy (n = 117), with patients in the active chemotherapy treatment arm receiving either a single agent or a combination containing bevacizumab (31%), irinotecan (31%), nitrosoureas (25%), carboplatin (13%), temozolomide (11%), or other agents (5%).

The primary endpoint of the trial was OS. NovoTTF Therapy demonstrated comparable OS to active chemotherapy, with a median OS of 6.6 versus 6.0 months, respectively (hazard ratio = 0.86 [95% confidence interval [CI], 0.66–1.12]; *P* = .27). The PFS6 (PFS rate at 6 months) was 21.4% versus 15.1%

(hazard ratio 0.81 [95% CI, 0.60-1.09];  $P = .13$ ), and the overall response rate was 14.0% versus 9.6% ( $P = 0.19$ ) for NovoTTF Therapy compared to active chemotherapy, respectively. The safety analyses favored NovoTTF Therapy, with severe adverse events occurring in 6% and 16% ( $P = .022$ ) of patients treated with NovoTTF Therapy and active chemotherapy, respectively.<sup>13</sup>

In the phase III trial, the median adherence to NovoTTF Therapy was 86% (range, 41%–98%) of the time ( $n = 116$ ), measured by a log file in the device that records time on therapy. This translated into a mean use of 20.6 hours per day. In the NovoTTF Therapy group, 93 (78%) patients completed 4 weeks of therapy (one cycle), with 27 (23%) discontinuing treatment within cycle 1, due to non-adherence or inability to handle the device.<sup>13</sup> Adherence with NovoTTF Therapy was the main predictor of improved OS in this trial, with patients who used the device for more than 18 hours a day living significantly longer than those who used it for less than 18 hours a day (7.8 months *v* 4.5 months,  $P < .05$ , respectively).<sup>12</sup> The most common device-related adverse events were grade 1 and 2 dermatologic adverse events (dAEs) of the scalp beneath the arrays, occurring in 18 patients or 16% (all grades; 2% grade 2) and no grade 3 or 4 dAEs. Skin ulceration was observed in one patient (<1%). All dAEs were reversible and did not result in discontinuation of patients from study. Other device-related AEs included headache (3%), malaise (2%), muscle twitching (1%), and fall (1%). Systemic toxicities including grade 3/4 hematologic (17%), gastrointestinal (17%), and infections (8% of patients) were significantly more frequent in chemotherapy-treated patients, compared to 3%, 4%, and 4%, respectively, for patients receiving NovoTTF Therapy ( $P < .05$ ; Fisher exact test).<sup>13</sup>

Quality-of-life was analyzed in patients who remained on therapy for >3 months and for whom quality-of-life data were available ( $n = 63$ , 27%). Whereas no differences in global health and social functioning between NovoTTF Therapy and active chemotherapy were observed, cognitive, social, role, and emotional functioning were all higher in the NovoTTF Therapy-treated group, while their physical functioning was slightly worse when compared to the chemotherapy treatment group. Symptoms that were reported by patients to be more severe with chemotherapy than with NovoTTF Therapy included appetite loss, diarrhea, constipation, nausea/vomiting, pain, and fatigue.<sup>13</sup>

Because the dAEs observed with NovoTTF Therapy are unique to this novel oncologic treatment modality, and treatment continuity is critical for better response to therapy, there is a need for improved nomenclature, preventive and management

strategies, and the identification of risk factors. In addition, the current Common Terminology Criteria for Adverse Events (CTCAE) version 4.0 grading criteria for the skin and subcutaneous tissue disorders; injury, poisoning and procedural complications; and infections and infestations system organ classes do not adequately describe or characterize the dAEs seen with NovoTTF Therapy.<sup>23–25</sup> Efforts to improve the nosology will help communication between healthcare providers and will also improve the description and grading of these dAEs in current and future clinical trials. Similarly, the development of management strategies for dAEs will help maintain patient quality-of-life and adherence to NovoTTF Therapy.

## BASIC PATHOPHYSIOLOGY OF SKIN AND HAIR

In order to understand pathogenic mechanisms underlying dAEs and to develop effective interventions, it is important to recognize that the skin is a complex, mitotically active, multi-layered organ composed of multiple cell types with various functions.<sup>26</sup> Structurally, the skin is composed of three layers: (1) the epidermis, which functions as a permeability and protective barrier and as an organ for immune surveillance; (2) the dermis, which provides the structural support to the skin and contains an extensive lymphatic and neurovascular network; and (3) the hypodermis and the associated subcutaneous fat, both of which provide insulation and contain blood vessels and nerves (Figure 3). All three of these layers function together to form a physical permeability barrier that protects the body from pathogenic microbes and ultraviolet radiation, regulates temperature, allows for the transduction of sensations, repairs wounds, and contributes to an individual's physical appearance and sense of self.<sup>27</sup> Although the epidermis and its outer stratum corneum provide the initial physical barrier to the environment, the structural integrity of skin as a whole is supported primarily by the dermis and hypodermis.<sup>28</sup>

The epidermis is the outermost layer of the skin. It is the only skin layer in direct contact with the hydrogel covering the ceramic discs and the adhesive tape of the bandage holding the transducer arrays in position. The epidermis is a continually renewing structure that gives rise to appendages such as pilosebaceous units (hair follicles), nails, and sweat glands. Epidermal appendages also provide special protective or sensory functions. The epidermis ranges in thickness from 50  $\mu\text{m}$  to 1.5 mm, as compared with the 1.5- to 4.0-mm thickness of the dermis.<sup>29</sup> More than 80% of cells in the epidermis are keratinocytes.

**Figure 3.** Schematic representation of human skin structure and cell population. The skin comprises three main layers: the epidermis, dermis, and hypodermis. The resident cell populations and various structures present throughout the skin allow for maintenance of an efficient barrier against water loss and protection against threats such as ultraviolet radiation (UVR) and microbial pathogens. The blood and lymph vessels allow for the migration of immune cells in and out of the skin, so that the cell population of the skin is constantly in a state of flux, in response to the demands of the cutaneous inflammatory and immune systems. Reprinted by permission from Macmillan Publishers Ltd: Nature (MacNeil S. Progress and opportunities for tissue-engineered skin. *Nature*. 2007;445:874-80), copyright 2007.

In humans, the normal doubling time for keratinocytes is 24 hours, and the transit time for a keratinocyte in the basal layer, from the time it loses contact with the basal layer to the time it enters the stratum corneum (outermost layer in the epidermis), is at least 14 days.<sup>30</sup> Transit through the stratum corneum and subsequent desquamation require another 14 days.<sup>30</sup> Intercalated among the keratinocytes at different levels are other cells—melanocytes, Langerhans cells, and Merkel cells. Additional cells, including lymphocytes, are temporary residents of the epidermis and are rare in normal skin. The innate immune system of the skin, which comprises antigen-presenting cells and circulating immune cells, provides additional antimicrobial functions.

Pathologic changes in the skin exposed to NovoTTF Therapy can occur or become exacerbated as a result of a number of different stimuli. These include repetitive mechanical trauma (as in the application and removal of the arrays<sup>31</sup> or shaving<sup>32</sup>) resulting in erosions, inflammation (from the hydrogel covering the ceramic discs or adhesive<sup>33</sup> or moisture from eccrine sweat or ambient humidity<sup>34</sup>), infection (as in bacterial folliculitis or impetigo<sup>35</sup>), wound healing (surgical scars or delayed healing associated with the use of bevacizumab<sup>36,37</sup>), and

ultraviolet (UV) radiation damage resulting in atrophy and actinic keratoses.<sup>38</sup>

Erosions are moist, circumscribed, depressed lesions that result from loss of a portion or all of the viable epidermis, with mild bleeding and associated with pain or burning.<sup>39</sup> Erosions may result from trauma related to the repeated removal of the arrays or shaving, inflammation and maceration from sweat-derived moisture, rupture of vesicles or bullae from infection, or epidermal necrosis from altered perfusion due to pressure of the arrays. In general, erosions do not result in a scar unless they become secondarily infected.

Dermatitis is a nonspecific term denoting skin inflammation, presenting with edema and erythema, followed by scaling. With NovoTTF Therapy, two types of dermatitis may develop. The first, representing approximately 20% of new cases of contact dermatitis, is allergic contact dermatitis (ACD), a cutaneous inflammatory reaction caused by contact with a specific exogenous allergen to which a person has been sensitized.<sup>40</sup> The second is irritant contact dermatitis (ICD), a nonspecific inflammation of the skin in response to direct chemical damage to epidermal cells and the release of inflammatory chemokines. These two types of dermatitis have unique clinical and pathophysiological characteristics. In ACD, following contact with an allergen (more than 3,700 chemicals have been identified as culprits of ACD<sup>41</sup>), the skin reacts with inflammation and the severity of the dermatitis can range from mild and temporary to severe and persistent. In the latter case, the dermatitis may not resolve unless treated, even if the offending allergen has been withdrawn. When ACD is suspected, allergen identification through epicutaneous patch testing has been demonstrated to improve quality-of-life,<sup>42</sup> as it allows for identification of the condition and avoidance of the causal allergen. In oncology patients, patch testing may not always be feasible due to the frequency of visits necessary (usually four) and concomitant medications that hinder the interpretation of patch testing (ie, corticosteroids, immunosuppressants). In these cases, a provocative use test (PUT) may identify the culprit in some cases.<sup>43</sup>

In ACD, the symptoms will not resolve unless the offending agent is removed and the area is treated with a topical corticosteroid, while ICD will resolve a few days after the culprit is removed. As noted above, ICD is a nonspecific inflammation of the skin manifested by erythema, edema, pruritus or burning, and scaling as a response to direct chemical damage.<sup>44</sup> Thus, in ICD, removal of the culprit is the only treatment necessary.

A more severe dAE is an ulcer, a lesion in which the epidermis and the dermis have been destroyed. Ulcers are usually round and their borders are well

defined. The base of an ulcer may be clean or necrotic and may contain granulation tissue. A discharge is usually indicative of infection and may be purulent, granular, or malodorous. Surrounding skin may be altered. During healing, the ulcer will form a crust composed of dried serum, blood, or exudate. The color of the crust is important: yellow-brown from a dried serous secretion; yellowish-green from a purulent secretion; and reddish-black from a hemorrhagic secretion. Ulcers may result in scarring.

Infections are common in skin and soft tissues given the abundance of microbes present in these structures.<sup>45</sup> A pustule is a circumscribed, raised lesion in the epidermis containing pus. Pus is composed of leukocytes and cellular debris (yellow color) and may contain bacteria (greenish-yellow color) or be sterile (white color). Pustules may contain a hair at the center, may vary in size, and may coalesce to form plaques of pus. Pustules may be confused with vesicles and bullae, which are fluid-filled lesions that are not always infected. Friction vesicles or bullae with clear contents may occur with shear forces on the epidermis or initially with viral infections, whereas those resulting from bacterial infections or late-stage viral infections will have yellow-greenish contents. In cases of bacterial infections resulting in bullae, the term "bullous impetigo" is used.

Scars arise from fibrous tissue proliferations that replace previously normal skin after a wound or ulceration disrupts the integrity of the skin. Surgical scars may retain a deeper pink or red color for months after a surgical procedure, and hairs are usually absent. The blood flow in scars is altered due to excess fibrous tissue deposition, making them susceptible to dAEs with NovoTTF Therapy use when the ceramic discs are placed immediately over them. Similarly, skin scarring, in the form of atrophy and absence of hair follicles, may develop after radiation therapy and may place these areas at higher risk for dAEs.

The use of NovoTTF Therapy involves placement of the transducer arrays directly onto the scalp for at least 18 hours a day. The arrays are left in place for 3–4 days before they are replaced with new arrays that are relocated on the scalp, the latter practice serves to minimize direct contact over the same areas of skin. Prolonged contact with the arrays poses unique chemical, mechanical, moisture, and thermal-related stresses on skin which may account for the development of dAEs. Consequently, continuous application of the transducer arrays without timely exchanges may cause the development of distinct dAEs on the scalp characterized by inflammation and, in some cases, associated with erosions, ulcers, and secondary infections.

The quality of the array-to-scalp contact is negatively affected by hair growth. The scalp contains approximately 100,000 hair follicles. These hair follicles are part

of pilosebaceous units, which contain hair shaft-forming cells, sebaceous glands, and arrector pili muscles. During hair growth, the preceding hair shaft is pushed up and out by a new shaft and results in shedding (normally, approximately 100 strands of hair are shed from the scalp every day).<sup>46</sup> Hair grows approximately 5–12.5 mm every month or 0.2–0.5 mm per day, which results in outward pressure on the adhered transducer arrays and requires repeated shaving at every array replacement (every 3–4 days). This is because an increased distance between the arrays and skin will allow an air gap to form, with air being an insulator for electric fields, and will affect the delivery of TTF fields.

## CHARACTERIZATION OF DERMATOLOGIC ADVERSE EVENTS

In order to characterize the dAEs, data from patients using NovoTTF Therapy were analyzed with a focus on skin-related AEs (including photographs of the scalp reviewed by a dermatologist) from the completed phase III trial (EF-11) of NovoTTF Therapy (n = 116 patients),<sup>13</sup> as well as from those patients with AEs submitted in the post-marketing surveillance program (n = 570 patients). The ongoing phase IV post-approval study in rGB (EF-19; NCT01756729) has not had sufficient enrollment at present to further define dAEs adequately.

Types of dermatologic adverse events were characterized, and associated patient data (if available) were reviewed, including time to development of dAE, clinical presentation, risk factors, and management strategies employed.

In the phase III trial (EF-11) 16% of patients (18 of 116 patients) had grade 1 or 2 dAEs and there was a 1% incidence of skin ulcer (1 of 116 patients). There were no grade 3 or 4 dAEs. Time to dAE onset was 2–6 weeks. These events were graded according to the CTCAE version 3.0. However, this version of the CTCAE did not allow for adequate characterization of the dAEs seen with NovoTTF Therapy. As a result, all dAEs were grouped into the same category.

Although the information available from the post-marketing surveillance program does not allow for detailed grading, 21.8% of patients (156 of 570 patients) had non-serious dAEs, with some patients reporting more than one event. There was a 0.7% incidence of skin ulcer (4 of 570 patients). The median time to dAE onset was 32.5 days (range of 2–520 days). Patients in this setting have reported the need for treatment interruptions or discontinuation of NovoTTF Therapy due to dAEs, but the exact percentage is not known because the post-marketing program is a "self report" program. This latter issue highlights the need for dermatologic management guidelines when NovoTTF Therapy is utilized in

**Table 1. Types and Potential Causes of Dermatologic Adverse Events**

Adverse Event	Potential Cause
Irritant contact dermatitis	Chemical irritation from hydrogel, moisture, and/or alcohol
Allergic contact dermatitis	Allergy to tape and/or hydrogel
Erosion	Mechanical trauma from shaving and/or array pressure/removal
Ulcer	Decreased perfusion from array pressure (especially in areas overlying scars/hardware/prior radiation)
Skin infection/pustules	Secondary bacterial infection

clinical practice outside of the carefully managed setting of a clinical trial.

A review of scalp photographs from patients on the EF-11 trial and from the post-marketing program (when available) by a dermatologist (M.E.L) allowed for the characterization of these dAEs. The clinical presentation of dAEs associated with NovoTTF Therapy can be divided into four major categories: dermatitis (allergic or irritant), erosion, infection, and ulcer (Table 1 and Figures 4–7).

In addition to the above findings, a review of patient data identified the following risk factors that may be associated with NovoTTF Therapy dAEs: (1) placement of ceramic disc(s) from the transducer arrays on the scalp overlying scars or craniotomy hardware; (2) history of contact dermatitis to materials used in the composition of array skin contact materials (ie, tape adhesive or hydrogel); (3) hyperhidrosis (excessive sweating) from hot, humid weather, fever, or occlusive wigs; (4) previous skin exposure to UV or ionizing radiation; (5) high doses or recent change in systemic corticosteroids; or (6) concurrent administration of systemic anticancer agent (eg, chemotherapeutics, biologics, or targeted therapeutics).

## MANAGEMENT OF DERMATOLOGIC ADVERSE EVENTS

The management of the dAEs associated with NovoTTF Therapy can be divided into prophylactic and treatment interventions.

### Prophylactic Interventions

Based on the clinical trial and post-marketing experience to date with NovoTTF Therapy, prophylactic interventions that decrease the risk of dAEs are divided into five categories: (1) patient and caregiver

A

B

**Figure 4.** Contact dermatitis (may or may not be symptomatic). (A) Erythema from scalp irritation that was caused by the adhesive tapes or hydrogel. The allergic dermatitis resolved with the application of a topical corticosteroid. (60-year-old man who had been on temozolomide and NovoTTF Therapy for 7 months). (B) Irritant reaction on the right side of scalp with erythema corresponding to the three strips of hydrogel on the transducer arrays. This adverse event occurred during the hottest days in the summer and was a result of a combination of high ambient temperature, increased humidity, excessive sweating, and patient sleeping on the right side of her head. Treatment required 1-2 weeks of device interruption and use of a topical corticosteroid (65-year-old woman who had been on NovoTTF Therapy for 2 months).

education, (2) scalp preparation, (3) infection prevention, (4) avoidance of scars and craniotomy hardware, and (5) array relocation. Table 2 provides a summary of these practices for use by the patient or caregiver.

### Patient and Caregiver Education

**Scalp preparation.** This basic step is critical to ensure good array-to-scalp contact, which will lower the risk of skin irritation and optimize delivery of the TTFields. Factors that are known to affect array-to-scalp contact include hair length (determined by proper and

**Figure 5.** Dermatologic erosions and skin infection (folliculitis) in a 60-year-old man who had been on temozolomide and NovoTTF Therapy for 3 months.

timely shaving), moisture from sweat (determined by eccrine sweating on the scalp), the presence of sebum or the degree of "oiliness" of the scalp (determined by individual patient skin characteristics and removal prior to array placement), and the duration of skin contact with the same set of arrays.

For removing hair from the scalp, an electric razor is recommended because it offers a smaller risk of cuts as compared to a straight blade razor. However, in some patients, the use of an electric razor may actually lead to an increase in folliculitis due to the pulling and tension exerted on the hair while it is being cut. If this is the case, patients may use a straight blade razor while great care is taken to avoid skin cuts. The closeness of the shave can be tested by running a piece of gauze or a cotton ball, wet with 70% isopropyl alcohol, across the shaved scalp. If there is detectable friction or resistance, a closer shave is required.

After shaving, washing the scalp with a mild, fragrance-free shampoo (eg, baby shampoo) will remove some of the sebum of the skin that can interfere with array-to-scalp contact. Dandruff shampoos (which contain pyrithione zinc) also can be used and may offer additional benefit because they have antimicrobial properties. Finally, wiping the skin with 70% isopropyl alcohol will help to remove the naturally occurring scalp sebum, resulting in better contact of the arrays to the scalp. When using alcohol, it is important to avoid contact with areas of dermatitis, erosions, or ulcers, as the alcohol may further irritate the skin.

On subsequent applications of the arrays, use of mineral oil before shaving is recommended because the oil can remove adhesive residues from the prior set of arrays. This will allow for adequate cleansing of the scalp and prevent the accumulation of bacteria and scaly skin.

A

B

**Figure 6.** Skin infection/folliculitis. (A) Folliculitis (62-year-old man after receiving NovoTTF Therapy for 4 weeks). (B) Skin infection (41-year-old woman after receiving NovoTTF Therapy for 3.5 weeks).

**Infection prevention.** The arrays are provided in individual sterile packages to minimize infection risk. Patients and their caregivers are advised to wash their hands prior to application and removal of the transducer arrays. The scalp should be washed with shampoo between array exchanges. The electric

**Figure 7.** Skin ulceration. Note how the arrays are arranged around the site of the ulcer (61-year-old man after receiving NovoTTF Therapy for 2 weeks).

razor should be cleaned (following manufacturer instructions for cleaning) on a regular basis and should not be shared with others.

**Transducer array application.** Arrays are placed on the scalp according to the transducer array layout plan, which is based on head size measurements, tumor size, and tumor location. The ceramic discs of the arrays should not be placed directly over implanted craniotomy closure hardware or surgical scars. Placement of the ceramic disc over a screw or plate may lead to subsequent skin breakdown, erosion, or ulceration.

Every time a set of arrays is changed (approximately every 3–4 days) the position of the arrays should be shifted approximately 0.75 inches from the last location, so that the hydrogel layer is between the prior contact sites. The ceramic discs will leave a slight indentation on the surface of the scalp, allowing patients and caregivers to readily see where to position the new set of arrays. On the next transducer array exchange, arrays should be shifted back to the

**Table 2. Preventive Strategies for Dermatologic Adverse Events**

Category	Guideline for Patient/Caregiver
Shaving and preparation of the scalp	<ul style="list-style-type: none"> <li>• Proper hand washing prior to preparing the scalp for array application</li> <li>• Take time shaving the scalp using gentle but firm circular motions</li> <li>• Ensure a close shave prior to applying the arrays</li> <li>• Cleaning the electric razor <i>after</i> every shave is important to lessen the risk of skin infection</li> <li>• Wash scalp with fragrance-free, mild shampoo (eg, baby shampoo); seborrheic dermatitis shampoo can also be used as it has antibacterial properties (eg, pyrithione zinc 2%, ciclopirox 1%, ketoconazole 2%).</li> <li>• Ensure scalp is completely dry before applying a new set of arrays</li> </ul>
Use of isopropyl (70%) alcohol	<ul style="list-style-type: none"> <li>• Use of first aid antiseptic rubbing alcohol (70% isopropyl alcohol) prior to array application is a necessary step to remove naturally occurring scalp oils, resulting in better adherence of the arrays to the scalp</li> <li>• After shaving and before placing the arrays, wipe the scalp with a gauze or cotton ball soaked in first aid antiseptic rubbing alcohol (70% isopropyl alcohol)</li> <li>• Avoid areas of skin irritation, as the first aid antiseptic rubbing alcohol (70% isopropyl alcohol) may further irritate the skin</li> </ul>
Transducer array exchanges	<ul style="list-style-type: none"> <li>• Change arrays on a regular basis (at least every 3-4 days)</li> <li>• When removing the arrays, avoid “pulling” on the skin and take approximately 60 seconds to remove each array</li> <li>• Using mineral (baby) oil on the edges of the array may make the removal of the adhesive tape easier and less irritating to the skin</li> <li>• To remove leftover array adhesive, use gauze or cotton ball soaked in mineral (baby) oil or pour into hands and gently rub scalp in areas of remaining adhesive</li> <li>• Pay close attention to the scalp at each array exchange and notify the doctor/nurse if there are signs of skin irritation or open areas, in order to receive information on how to treat the affected area(s). Taking a picture of the affected area(s) on the scalp and sharing with doctor/nurse is advised</li> </ul>

**Figure 8.** Preventive measures. Illustration of shifting transducer arrays at each array exchange.

previous position. Shifting the arrays every time they are changed will minimize continuous exposure of the same portion of the scalp to the hydrogel that may lead to subsequent dAEs (Figure 8).

**Transducer array removal.** Each set of arrays should be exchanged at least every 3–4 days. More frequent array exchanges may be required in some patients. Careful removal of arrays (taking approximately 60 seconds to remove each array) will lessen irritation to the skin. When removing the arrays from the scalp, excessive force should be avoided. In addition, applying mineral oil to the edges of the arrays may make removal easier and less irritating to the skin. The use of mineral oil (applied via a soaked gauze or cotton ball or directly to the scalp by hand) will help to ensure complete removal of array adhesive and minimize damage to the skin. Forceful rubbing of the scalp to remove array adhesive should be avoided.

Examination of the scalp at each array exchange by patients and/or caregivers will allow for identification of asymptomatic dAEs and early intervention after consultation with the health care provider. Taking photographs of the affected area(s) on the scalp to review with the physician or nurse in subsequent office visits, or for more urgent consultation and intervention, is recommended.

**Additional considerations.** Because the array hydrogel is hydrophilic, it may become partially liquified (glutinous) during warmer weather or after intense physical activity because the hydrogel will absorb sweat. This may necessitate more frequent changes of the arrays (eg, every 1–2 days). Some medications such as corticosteroids (after prolonged use), systemic chemotherapies, and certain targeted therapies (ie, vascular endothelial growth factor [VEGF] inhibitors such as bevacizumab) may increase the risk of skin reaction or affect wound healing. Ongoing clinical trials evaluating NovoTTF Therapy in combination with other systemic therapies will better define the safety of NovoTTF Therapy with concurrent therapies. A recent presentation of data

from a cohort of 20 patients treated with combined NovoTTF Therapy and bevacizumab did not suggest any concern regarding adverse events in general and dAEs specifically.<sup>47</sup>

### Treatment Interventions—Pharmacologic and Treatment Interruption

The NovoTTF-100A System treatment parameters (frequency and intensity), based on preclinical studies, are preset into the device; therefore, no "dose modifications" can be made for the management of adverse events. Thus, in addition to prophylactic interventions, the primary options for treatment of dAEs are based on the type of dAEs and include topical therapies, relocation of arrays, and avoidance of affected skin whenever possible. Although array shifting to different scalp locations is a recommended prophylactic measure, this can also be used if there are existing sites of dAEs by shifting the arrays around the existing injury sites (Figures 7 and 8). If the area of skin irritation is such that shifting of the arrays is not feasible, the area(s) of skin irritation can be protected with sterile nonadherent dressing pads (Figure 9), while avoiding placement of the ceramic discs directly over these areas. Infrequently, oral antibiotics are required along with treatment interruption for intolerable grade 2 or grade 3 dAEs.

#### Pharmacologic Treatment

The primary treatments for NovoTTF Therapy-related dAEs are topical corticosteroids and topical antibiotics (Figure 10). If there are signs of dermatitis (Table 1), a topical corticosteroid is recommended. However, when the epidermal barrier is compromised (erosions) or when there are signs of infection (Table 3), topical antibiotics are recommended. Obtaining bacterial skin cultures prior to initiating antibiotic therapy is helpful to identify the causative microorganism(s) and to ensure appropriate antimicrobial coverage.

Topical therapies may be applied only at the time of transducer array exchanges (approximately every

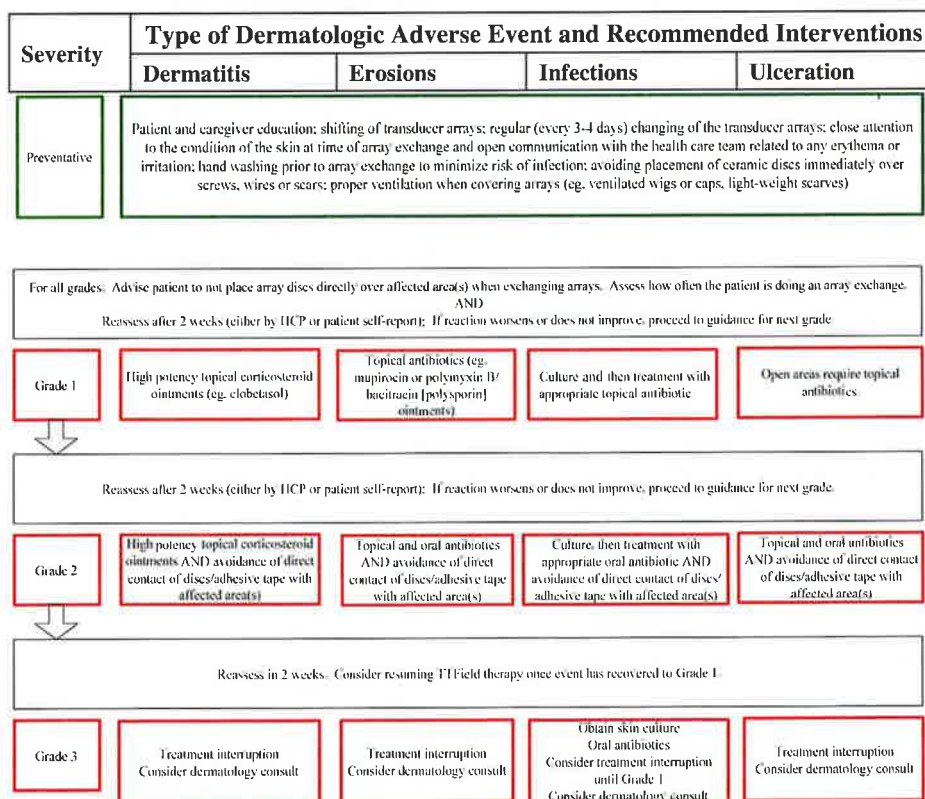

**Figure 9.** Example of protection of sites of dermatologic adverse events with small sterile nonstick gauze barriers. (Note: gauze should not be directly beneath any of the array ceramic disks.)

3–4 days); therefore, high-potency corticosteroid ointments (eg, clobetasol 0.05%, betamethasone 0.05%) are recommended to maximize skin absorption and pharmacological action. Because creams and ointments contain lipid ingredients, it is important that any topical residue left on the skin be removed with scalp washing or 70% isopropyl

alcohol as this residue will interfere with the adherence of the arrays to the scalp and hence may affect transmission of the TTFields. The use of topical or oral antibiotics should be selected based on the spectrum of activity for the skin flora on the scalp (eg, mupirocin or polymyxin B/bacitracin for topical preparations). Use of neomycin-containing topical antibiotics is discouraged because of the relatively high incidence of contact dermatitis in the general population. It is recommended that topical therapies are applied and left on the scalp for a minimum of 15–30 minutes before removing any residual cream/ointment with 70% isopropyl alcohol or re-washing of the scalp and reapplication and relocation of the arrays.

### Treatment Interruptions

For intolerable grade 2 and grade 3 dAEs, treatment interruption in conjunction with topical therapies is recommended. It should be noted that reapplication and relocation of the arrays is possible after treatment interruptions due to intolerable grade 2 or grade 3 events. Anecdotal data suggest that interruption for 2–7 days is frequently sufficient for resolution of the dAEs. This is consistent with the turnover rate of cells in the epidermis as described previously. Patients with prior dAEs may be more likely to have a recurrence of

**Figure 10.** Treatment algorithm for dermatologic adverse events associated with the use of NovoTTF Therapy.

**Table 3. Signs of Skin Events Based on Underlying Pathogenesis**

Dermatitis	Skin Infection	Mechanical	Ischemia
Erythema	Erythema	Erosions	Ulcers
Scaling	Discharge	Abrasions	Pain
Erosions	Pustules	Lacerations	
Edema	Pain	Pain/burning	
Pruritus	Yellow/green crusting		

dAEs once the arrays are reapplied, so patient education and use of prophylactic measures upon rechallenge are recommended.

Duration of treatment interruptions should be minimized, as treatment adherence is correlated with NovoTTF Therapy efficacy. A post hoc, subset analysis from the phase III trial (EF-11) demonstrated a higher OS in patients that were treated for 75% or more of the time (approximately 18 hours per day on average over the course of a month) compared to those patients treated for less than 75% of the time on average (OS 7.8 months *v* 4.5 months, respectively,  $P = .04$ ).<sup>12</sup>

## DISCUSSION AND CONCLUSIONS

NovoTTF Therapy represents a treatment modality for rGB that produces effects on multiple phases of the cell cycle through the use of alternating electric fields (TTFields). It has undergone clinical comparison with systemic chemotherapies in a phase III trial in which NovoTTF Therapy demonstrated a comparable survival benefit, but with improved patient function in cognitive, social, role, and emotional measures, along with decreased systemic adverse events such as anorexia, fatigue, nausea, vomiting.<sup>13</sup> A higher OS was seen in patients that were treated for 75% or more of the time (approximately 18 hours per day on average over the course of a month).<sup>12</sup> Due to its unique mechanism of action and the epicutaneous delivery system with transducer arrays applied on the scalp, dAEs are the most common adverse events seen with this therapy. As with any AE, these dAEs can impact the patients' quality-of-life, adherence to therapy, and medical costs.

A standardized system for clinical description and grading of dAEs related to NovoTTF Therapy is critical in order to ensure proper communication between healthcare providers and to identify appropriate interventions. Characterization of the dAEs observed with NovoTTF Therapy revealed that there are four types of events that differ clinically and that require distinct preventive and active management strategies. These are: (1) irritant contact dermatitis caused by chemical irritation from sweat, hydrogel, and/or alcohol; (2) allergic (immunologic) contact dermatitis resulting from a delayed type

hypersensitivity to tape and/or hydrogel; (3) mechanical erosions from cuts induced by shaving and stripping injury from array removal; (4) ulcers from decreased perfusion where the ceramic discs compress the skin, especially over scars or hardware; and (5) skin infections that are bacterial in origin. Taken as a whole, the pathogenic mechanisms underlying dAEs with NovoTTF Therapy are probably related to the occlusive nature of the adhesive tape of the bandages and hydrogel-covered ceramic discs, rather than to the TTFields generated by the device.

Similar dAEs, including allergic and irritant dermatitis, ulcers, and skin infections, have been described with other devices that are directly applied onto skin, such as abdominal appliances for stomas and ileal conduits.<sup>48,49</sup> To date, there are no randomized controlled trials for the prevention or management of dAEs from the use of abdominal appliances, yet there are abundant anecdotal and empirical data. Indeed, more than 30% of colostomy patients and more than 70% of urostomy and ileostomy patients develop dAEs; however, this unusually high incidence is likely related in part to the enzymatic activity produced by bacteria in the urine and stool. Approximately 30% of visits to stoma nurses are related to skin complications, underscoring the importance of dAEs with epicutaneous devices.<sup>50</sup> Consequently, a similar rationale for the treatment of NovoTTF Therapy-related dAEs has been devised here.

Correct identification of AEs will dictate specific therapies towards their treatment and prevention of recurrence. While most dAEs may be managed with topical interventions and relocation of the arrays, preventive strategies are critical in minimizing recurrent and additional dAEs. For bacterial infections, a swab culture along with topical or oral antibiotics are needed. For erosions or abrasions care should be taken to avoid mechanical trauma and to isolate the lesion from further injury. For ulcers, it is important to remove arrays from the site of the ulcer since they may decrease blood perfusion and interfere with proper wound care. Due to the relatively protracted processes of skin proliferation and wound healing, improvement and resolution of dAEs usually takes at least 7–14 days. Thus, at a minimum, interventions to treat dAEs must continue during this time frame. One notable

**Table 4. Proposed Grading for Device-Related Dermatologic Adverse Events**

Grade	Description*
1	Asymptomatic or mild symptoms; topical therapy indicated (eg, antibiotic, corticosteroid).
2	Moderate symptoms AND topical and systemic therapy indicated (eg, antibiotic, corticosteroid); device application interruption; temporary relocation of device to avoid affected skin areas; or isolation by dressings of affected areas indicated.
3	Severe or medically significant but not immediately life-threatening AND topical and systemic therapy indicated (eg, antibiotic, corticosteroid); operative intervention indicated; hospitalization or prolongation of existing hospitalization indicated; device application interruption indicated.
4	Life-threatening consequences: urgent intervention indicated; device discontinuation indicated.

\* A cutaneous device-related dermatologic event is defined as a disorder characterized by dermatitis, skin infection, erosion, or ulcer related to the noninvasive use of a medical device.

exception is the development of ulcerations. Ulcerations involve the dermis and may require surgical intervention and may demand a longer time to heal even with appropriate wound care.

Treatment interventions will depend on the type and the severity of AE. The severity of AEs is defined by the National Cancer Institute's CTCAE. At the time the phase III NovoTTF Therapy trial was conducted, the CTCAE version 3.0 was used to describe dAEs. Current and previous iterations of the CTCAE (versions 3.0 and 4.0) do not adequately capture the clinical characteristics and management of NovoTTF Therapy-induced dAE.<sup>13</sup> A proposed grading system based on the CTCAE has been described here that includes specific terms related to NovoTTF Therapy-related dAEs (Table 4), including the need for device application interruption or relocation, application of dressings over the affected skin, and indications for topical or systemic therapies. This system may allow for more consistent grading in forthcoming trials investigating the efficacy of NovoTTF Therapy, supportive care interventions and daily clinical care.

Most dAEs can be prevented or managed with the skin care recommendations set forth in this manuscript. With the increasing adoption of NovoTTF Therapy for rGB, proper prevention and timely management of dAEs is crucial to maintain patient quality-of-life, to ensure consistent use of the device, and to maximize the clinical benefit of NovoTTF Therapy for patients with rGB.

# Clinical Practice Experience With NovoTTF-100A™ System for Glioblastoma: The Patient Registry Dataset (PRiDe)

Maciej M. Mrugala,<sup>a</sup> Herbert H. Engelhard,<sup>b</sup> David Dinh Tran,<sup>c</sup> Yvonne Kew,<sup>d</sup> Robert Cavaliere,<sup>e</sup> John L. Villano,<sup>f</sup> Daniela Annenelie Bota,<sup>g</sup> Jeremy Rudnick,<sup>h</sup> Ashley Love Sumrall,<sup>i</sup> Jay-Jiguang Zhu,<sup>j</sup> and Nicholas Butowski<sup>k</sup>

Recurrent glioblastoma multiforme (GBM) is a highly aggressive cancer with poor prognosis, and an overall survival of 6 to 7 months with optimal therapies. The NovoTTF-100A™ System is a novel antimitotic cancer therapy recently approved for the treatment of recurrent GBM, based on phase III (EF-11) trial results. The Patient Registry Dataset (PRiDe) is a post-marketing registry of all recurrent GBM patients who received NovoTTF Therapy in a real-world, clinical practice setting in the United States between 2011 and 2013. Data were collected from all adult patients with recurrent GBM who began commercial NovoTTF Therapy in the United States between October 2011 and November 2013. All patients provided written consent before treatment was started. Overall survival (OS) curves were constructed for PRiDe using the Kaplan-Meier method. Median OS in PRiDe was compared for patients stratified by average daily compliance ( $\geq 75\%$  v  $< 75\%$  per day) and other prognostic variables. Adverse events were also evaluated. Data from 457 recurrent GBM patients who received NovoTTF Therapy in 91 US cancer centers were analyzed. More patients in PRiDe than the EF-11 trial received NovoTTF Therapy for first recurrence (33% v 9%) and had received prior bevacizumab therapy (55.1% v 19%). Median OS was significantly longer with NovoTTF Therapy in clinical practice (PRiDe data set) than in the EF-11 trial (9.6 v 6.6 months; HR, 0.66; 95% CI, 0.05 to 0.86,  $P = .0003$ ). One- and 2-year OS rates were more than double for NovoTTF Therapy patients in PRiDe than in the EF-11 trial (1-year: 44% v 20%; 2-year: 30% v 9%). First and second versus third and subsequent recurrences, high Karnofsky performance status (KPS), and no prior bevacizumab use were favorable prognostic factors. No unexpected adverse events were detected in PRiDe.

As in the EF-11 trial, the most frequent adverse events were mild to moderate skin reactions associated with application of the NovoTTF Therapy transducer arrays. Results from PRiDe, together with those previously reported in the EF-11 trial, indicate that NovoTTF Therapy offers clinical benefit to patients with recurrent GBM. NovoTTF Therapy has high patient tolerability and favorable safety profile in the real-world, clinical practice setting.

Semin Oncol 41:S4-S13 © 2014 Published by Elsevier Inc.

**G**lioblastoma multiforme (GBM) is the most aggressive form of human glioma and accounts for approximately 60% to 70% of all malignant gliomas.<sup>1,2</sup> Based on data from the 2013 Central Brain Tumor Registry of the United States (CBTRUS) statistical report on primary brain and CNS tumors in the United States, an estimated 9,600 to 11,200 new cases of GBM will be diagnosed in 2014.<sup>1,2</sup> Virtually all patients with newly diagnosed GBM relapse despite maximal multimodality treatment,<sup>3</sup> with a median time to recurrence of approximately 7 months.<sup>4</sup> The prognosis for patients with recurrent GBM is even worse. The median progression-free survival (PFS) was only 9 weeks in the pre-bevacizumab era.<sup>5</sup> In 2009, bevacizumab received accelerated approval from the US Food and Drug Administration (FDA) for the treatment for recurrent GBM based on two single-arm studies with favorable response rates and PFS data.<sup>1,6,7</sup> Formal phase III data is not available in the recurrent setting, however phase III comparison of bevacizumab versus placebo in newly diagnosed glioblastoma patients failed to demonstrate prolongation of survival with bevacizumab.<sup>1,8</sup> A major challenge in treatment of recurrent GBM, particularly with bevacizumab, is that the tumor eventually develops resistance to the drug. Moreover, bevacizumab-treated tumors may convert to a more aggressive phenotype and exhibit infiltrative tumor growth as observed on magnetic resonance imaging (MRI).<sup>9,10</sup> Furthermore, patients with recurrent GBM who progress following bevacizumab therapy are typically resistant to subsequent cytotoxic chemotherapies.<sup>1,11,12</sup> Therefore, new treatments that can offer a different mechanism of action and potentially overcome treatment resistance are desperately needed.

The NovoTTF-100A™ System (Novocure, Ltd., Haifa, Israel) is a novel antimitotic cancer therapy approved in 2011 by the US FDA for the treatment of recurrent supratentorial GBM,<sup>13,14</sup> based on the results of a phase III trial comparing NovoTTF Therapy with best chemotherapy according to physician choice.<sup>15</sup> The unique mechanism of action of NovoTTF Therapy involves localized delivery of alternating low-intensity, intermediate-frequency,

tumor-treating fields (TTFields) via non-invasive transducer arrays attached to the patient's scalp.<sup>14</sup> In preclinical studies, TTFields have been shown to selectively kill or arrest the growth of rapidly dividing cancer cells including glioblastoma cell lines by disrupting both mitotic spindle formation and normal cytokinesis by interrupting cytoplasmic furrow formation.<sup>16–20</sup>

The pivotal phase III (EF-11) trial that led to FDA approval of the device compared NovoTTF Therapy (n = 120) with best chemotherapy according to physician's choice (n = 117) in recurrent GBM patients from 28 institutions in seven countries.<sup>15</sup> More than 80% of patients in the study had failed two or more prior chemotherapies, and 20% had experienced recurrence while on bevacizumab. Seventy-eight percent of the 116 patients who started NovoTTF Therapy completed at least one full-treatment course (4 weeks). The results demonstrated comparable median OS with NovoTTF Therapy compared with chemotherapy (6.6 v 6.0 months; hazard ratio [HR], 0.86; 95% confidence interval [CI], 0.66 to 1.12; *P* = .27), together with fewer severe adverse events (6% v 16%, *P* = .022) and improved quality-of-life measures for the NovoTTF Therapy arm compared with the chemotherapy arm. The most common adverse events with NovoTTF Therapy were mild to moderate skin irritation associated with the transducer arrays. Systemic adverse events commonly associated with chemotherapy were generally absent in patients receiving NovoTTF Therapy.

Given the mechanism of action of TTFields and the results of preclinical studies, optimal device compliance is required for therapeutic effectiveness with NovoTTF Therapy. NovoTTF Therapy does not have a half-life, therefore it requires continuous application to exert a therapeutic effect. This differs from systemic chemotherapy, which exerts anticancer effects between administrations due to the drug pharmacokinetics. Based on modeling of tumor growth kinetics and supporting preclinical and clinical data, NovoTTF Therapy must be administered almost "continuously" for at least 4 weeks in order to halt tumor growth and subsequently demonstrate an objective response.<sup>21,22</sup> Recommended administration of NovoTTF Therapy

is  $\geq 18$  hours per day for each 4-week treatment cycle.<sup>21</sup> A post hoc analysis of the phase III trial data recently showed significantly longer median OS in NovoTTF Therapy patients with a maximal monthly compliance rate  $\geq 75\%$  ( $\geq 18$  hours daily) versus those with a  $<75\%$  compliance rate (7.7 *v* 4.5 months,  $P = .042$ ) (see Kanner et al in this supplement). A recent responder analysis also demonstrated very high compliance rates  $>90\%$  in EF-11 responders.<sup>23</sup>

The Patient Registry Dataset (PRiDe) is a registry of 457 recurrent GBM patients who received NovoTTF Therapy in the clinical practice setting on the US commercial prescription-use program between October 2011 and November 2013. Patients treated in clinical trials often differ from those who receive treatment in the real-world setting due to patient selection criteria and frequently represent a less homogenous group. Hence registry data can be an important source of additional information about the efficacy and safety of a newly approved therapy. This report analyzes data from PRiDe to help us better understand the potential benefits of NovoTTF Therapy for patients with recurrent GBM, including analyses of median OS, tolerability, and the relationship between survival and compliance as well as other prognostic factors.

## METHODS

### Patients and Data Collection

PRiDe data were collected from all patients  $\geq 18$  years old with recurrent GBM who began commercial treatment with NovoTTF Therapy in the United States between October 2011 and November 2013. All participating patients provided written informed consent to use protected health information to advance the understanding of NovoTTF Therapy. Recurrent GBM was defined as histologically-confirmed, supratentorial GBM (World Health Organization grade IV astrocytoma) with radiologically confirmed evidence of disease progression, as defined by the Macdonald criteria,<sup>24</sup> following treatment with radiotherapy with or without concomitant and/or adjuvant chemotherapy. Patients who received NovoTTF Therapy were not restricted to the number or types of prior therapies or recurrences. Information about combination use of NovoTTF Therapy as part of the prescription-use program was not captured. Therefore some patients may have received combination therapy (chemotherapy or anti-vascular endothelial growth factor [VEGF] agents) rather than monotherapy.

Baseline characteristics were assessed by manual patient chart review. OS was collected using the Social Security Death Date Registry and obituaries. Novocure started collecting compliance data centrally

in January 2013, so such data are only available for under two thirds of patients in the registry. A monthly compliance assessment was performed for each patient by computer download of an internal log file which captures the cumulative amount of time therapy is delivered to the patient. Patient compliance was calculated as the average percentage of each day the system was delivering fields (out of each 24-hour period). In addition, other prognostic factors, such as the number of prior recurrences, age, KPS, prior bevacizumab use, and any debulking surgery were captured and analyzed. Adverse events were recorded prospectively according to National Cancer Institute Common Toxicity Criteria. Quality-of-life measures were not assessed in PRiDe.

### Statistical Analysis

The OS and treatment duration curves were constructed using the Kaplan-Meier method. OS in PRiDe was compared to OS for patients receiving NovoTTF Therapy or best chemotherapy in the phase III EF-11 trial (ITT population) using a log-rank (Mantel-Cox) test. Patient or disease characteristics prognostic for survival with NovoTTF Therapy were assessed using a Cox proportional hazards model ( $P$  value of .15 for significant interactions). Subgroup analyses were performed on patient/clinical characteristics found to be significantly correlated with OS. A log-rank test was used to compare the relationship between OS and daily compliance ( $<75\%$  *v*  $\geq 75\%$ ), prior debulking surgery (yes, no), KPS (90–100, 70–80, 10–60), recurrence number (1st, 2nd, 3rd–5th recurrence) and prior bevacizumab use (prior use *v* naïve).

## RESULTS

### Patient Characteristics

Four-hundred fifty-seven patients with recurrent GBM were treated with NovoTTF Therapy between October 2011 and November 2013 at 91 oncology centers. This population is more than three times the 120 subjects treated with NovoTTF monotherapy, as well as the 117 subjects treated with chemotherapy, in the phase III EF-11 trial, from which we were making a comparison. Baseline patient characteristics are presented in Table 1. Patient characteristics (age and gender) were generally similar in PRiDe and the two treatment groups in the EF-11 trial. Approximately one third of patients treated commercially with NovoTTF Therapy were women, which is an important observation given the perceived cosmetic considerations of head shaving and array placement.

**Table 1. Baseline Patient Characteristics in PRiDe and EF-11 Trial**

Characteristic		PRiDe NovoTTF Therapy (n = 457)	EF-11 NovoTTF Therapy (n = 120)	EF-11 Chemotherapy (n = 117)
Age (y)	Median (range)	55 (18–86)	54 (24–80)	54 (29–74)
Gender	Male	67.6%	77%	62%
	Female	32.4%	23%	38%
KPS	Median (range)	80 (10–100)	80 (50–100)	80 (50–100)
	10–60	19.0%	NA	NA
	70–80	46.6%	NA	NA
	90–100	30.9%	NA	NA
	Unknown	3.5%	NA	NA
Recurrence	Median (range)	2 (1–5)	2 (1–5)	2 (1–4)
	First	33.3%	9%	15%
	Second	26.9%	48%	46%
	Third to Fifth	27.4%	43%	39%
	Unknown	12.5%	0%	0%
Prior treatments	Bevacizumab	55.1%	19%	18%

	Debulking surgery	63.9%	79%	85%
	Carmustine wafers	3.7%	NA	NA

Abbreviations. KPS, Karnofsky performance status; NA, not available; RT, radiotherapy.

## Tolerability and Safety

No new adverse events were detected in PRiDe compared to those found in EF-11. The most common device-related adverse events associated with NovoTTF Therapy in the registry were skin reactions/irritation and heat sensations on the scalp beneath the transducer arrays (Table 2). Patients sometimes described these events as “warmth” or “tingling” sensations, none of which were associated with injury to the patient. Systemic adverse events, which were often associated with chemotherapy (eg, gastrointestinal, hematologic, and infectious adverse events), were rare for patients treated with NovoTTF Therapy in the registry.

## Survival Rates

Figure 1 presents Kaplan-Meier curves of OS for patients treated with NovoTTF Therapy in the clinical practice setting (PRiDe) and those who received NovoTTF Therapy or best chemotherapy as part of the EF-11 trial (ITT population; see Kanner et al in current supplement). Median OS on NovoTTF Therapy appeared to be markedly longer in PRiDe than in the EF-11 trial (9.6 v 6.6 months). Median OS was also significantly longer with NovoTTF Therapy in PRiDe than with best chemotherapy group in the EF-11 trial (9.6 v 6.0 months). One- and 2-year OS rates for NovoTTF Therapy patients in PRiDe were more than double those seen

with either NovoTTF Therapy or best chemotherapy in the EF-11 trial (Table 3).<sup>15,25</sup>

Median treatment duration for patients in PRiDe was 4.1 months (95% CI, 3.5–4.8). In comparison, the median treatment duration in the EF-11 study was 2.3 months (95% CI, 2.1–2.4) for NovoTTF Therapy arm and 2.1 months (95% CI, 2.0–2.9) for best chemotherapy. Figure 2 shows the fraction of NovoTTF Therapy patients still on treatment over time. Roughly 50% were still on NovoTTF Therapy after 4 months from treatment start, and roughly 10% were still on NovoTTF Therapy at 2 years after treatment start.

## Compliance as a Prognostic Factor and Its Relationship to OS

Because of the major difference in the OS in patients registered in PRiDe as compared to the OS of subjects treated with NovoTTF monotherapy in EF-11, we sought to identify the prognostic factors in the former cohort. The first prognostic factor we analyzed was NovoTTF treatment compliance because it was found to be prognostically important in EF-11 in a post hoc analysis. Compliance data were collected centrally starting in January 2013 and, therefore, were only available for 287 of the 457 patients (63%) in the registry. The median daily compliance was 70% for patients treated with NovoTTF Therapy in PRiDe (range, 12%–99%). One

**Table 2.** Adverse Events in Patients With Recurrent Glioblastoma Multiforme Treated With NovoTTF Therapy in PRiDe

Adverse event	Percentage of Patients PRiDe (n = 457)
Skin reaction	24.3
Heat sensation	11.3
Neurological disorder	10.4
Seizure	8.9
Electric sensation	7.7
Headache	5.7
Pain/discomfort	4.7

Psychiatric disorder	2.9
Gastrointestinal disorder	2.9
Fatigue	2.5
Vascular disorder	1.6
Weakness	1.4
Infections	1.4
Eye disorder	1.3

hundred twenty-seven (44%) achieved daily compliance of  $\geq 75\%$  of each day, while 160 (56%) had daily compliance of  $< 75\%$ . As illustrated in Figure 3, median OS was significantly longer in patients with a NovoTTF Therapy daily compliance  $\geq 75\%$  than in those with  $< 75\%$  daily compliance (13.5% *v* 4.0%; HR, 0.43; 95% CI, 0.29–0.63;  $P < .0001$ ).

**Figure 1.** Kaplan-Meier overall survival (OS) curves for patients with recurrent glioblastoma multiforme treated with NovoTTF Therapy in PRiDe or with NovoTTF Therapy or best chemotherapy in the EF-11 trial ( $P = .0003$ ).

## Other Prognostic Factors

The Cox proportional hazards model identified the presence or absence of debulking surgery, number of prior recurrences, compliance, KPS, and prior bevacizumab therapy as significant independent predictors of OS in patients treated with NovoTTF Therapy in PRiDe ( $P < .15$ ). Table 4 presents log-rank OS testing between patient subgroups in PRiDe for each of these prognostic factors; Figure 4 presents Kaplan-Meier survival curves for these same factors. First, no difference in median OS was observed between patients who did not have surgical debulking and those who did (8.9 *v* 9.8, respectively; HR, 1.1; 95% CI, 0.8–1.5;  $P = .7927$ ). Second, recurrent GBM patients treated with NovoTTF Therapy in clinical practice at their first recurrence experienced a significantly longer median OS as compared to patients treated at their second, third, or subsequent recurrence (20 months compared to 8.5 and 4.9 months, respectively; HR, 0.6; 95% CI, 0.4–0.9;  $P = 0.0271$  and HR, 0.3; 95% CI, 0.2–0.5;  $P < .0001$ ). It should be noted that a greater percentage of patients in PRiDe were at their first GBM recurrence compared with patients treated with NovoTTF Therapy or best chemotherapy in the EF-11 trial (33.3% *v* 9% and 15%, respectively). In addition, differences were also apparent between patients in PRiDe and those in the EF-11 trial with respect to prior treatments. More than half of NovoTTF Therapy patients in PRiDe had previously received bevacizumab (55.1%), compared with only 19% of NovoTTF monotherapy and 18% of best active chemotherapy cohorts in the EF-11 trial. Third, recurrent GBM patients with KPS  $\geq 90$  exhibited a near doubling of median OS compared with patients with a KPS of 70–80, median OS 14.8 versus 7.7 months, respectively, HR 0.6 (95% CI, 0.4–0.9),  $P = .0070$ . Lastly, the survival of bevacizumab-naïve patients was significantly longer compared to patients who had received prior bevacizumab before starting NovoTTF Therapy, with a respective median OS 13.4 versus 7.2 months, HR 0.5 (95% CI, 0.4–0.7),  $P < .0001$ . These data suggest that, within this

**Table 3.** One- and 2-Year Overall Survival Rates for Patients With Recurrent Glioblastoma Multiforme Treated With NovoTTF Therapy in PRiDe and EF-11 Trial, and With Best Chemotherapy in the EF-11 Trial

Endpoint	PRiDe NovoTTF Therapy (n = 457)	EF-11 NovoTTF Therapy (n = 120)	EF-11 Chemo- therapy (n = 117)

heterogeneous group of patients registered in PRiDe, there were subsets of patients who derived significant benefit from NovoTTF Therapy.

## DISCUSSION

The Patient Registry Dataset, or PRiDe, represents 457 unselected patients with recurrent GBM who received NovoTTF Therapy in a real-world, clinical practice setting across 91 cancer centers in the United States between October 2011 and November 2013. No new, unexpected adverse events were detected with NovoTTF Therapy in this cohort. Similar to the EF-11 trial,<sup>15</sup> the most common adverse events associated with NovoTTF Therapy were mild to moderate skin reactions localized to the scalp beneath the transducer arrays. These reactions were easily treated with topical corticosteroids or antibiotics, were not associated with serious injury to the scalp, and typically did not require interruption of treatment. Some patients in PRiDe reported subjective sensations beneath the transducer arrays, often described as “warmth” or “tingling.” These heat or electric sensations were captured as adverse events in PRiDe (“skin reaction”), but not in the EF-11 trial. These sensations occur when the contact between transducer arrays and the skin is suboptimal, and usually indicate the presence of hair regrowth. In these instances, re-shaving the head can re-establish optimal contact between the skin and transducer arrays. Furthermore, systemic adverse events commonly observed with chemotherapy were largely absent in patients treated with

NovoTTF Therapy in PRiDe as they were in the EF-11 trial.<sup>15</sup>

Patients receiving NovoTTF Therapy for recurrent GBM demonstrated a median OS of 9.6 months in clinical practice. This compares favorably to the reported median OS for the EF-11 pivotal trial cohort treated with NovoTTF monotherapy, where median OS was 6.6 months, and to OS of patients who received treatments for recurrent GBM in other clinical trials.<sup>26–29</sup> For example, recent reports of median OS in recurrent GBM patients treated with bevacizumab are in the range of 6 to 10.5 months,<sup>7,12,26–28,30</sup> and those treated with temozolomide in the range 6 to 9 months.<sup>31–33</sup> It should be noted that many of the longer term survival outcomes noted in clinical trials of bevacizumab and temozolomide in recurrent GBM included small sample sizes and none were randomized.

The difference between the OS seen in clinical practice and in the EF-11 trial may in part be due the greater percentage of patients with a first GBM recurrence in PRiDe versus patients in the EF-11 study (33.3% *v* 9%, respectively). This observation is also supported by a prior post hoc analysis of EF-11 that showed a significantly longer median OS in patients treated with NovoTTF Therapy at their first or second recurrence compared to those treated at third or subsequent recurrences. Furthermore, when used as intended (daily compliance  $\geq 75\%$  or  $\geq 18$  hours daily), the median OS for patients treated with NovoTTF Therapy in PRiDe was remarkably high at 13.5 months compared to only 4.0 months in those who had suboptimal compliance (daily compliance

**Figure 3.** Overall survival (OS) by daily compliance with NovoTTF Therapy for recurrent glioblastoma multiforme patients in PRiDe.

**Table 4.** Overall Survival (OS) in Patients With Recurrent Glioblastoma Multiforme Treated With NovoTTF Therapy in PRiDe Based on Prognostic Factors Significantly Correlated With OS in the Cox Proportional Hazards

Variable	Median OS (mo)	Hazard Ratio	P Value
<b>No. of recurrences</b>			
1st	20	—	—
2nd	8.5	0.6 (95% CI, 0.4–0.9)	.0271 <sup>a</sup>

Yes (any surgery)	9.8		

<sup>a</sup> First recurrence compared to 2nd recurrence.<sup>b</sup> First recurrence compared to 3rd–5th recurrence.<sup>c</sup> KPS 90–100 compared to KPS 70–80.<sup>d</sup> KPS 90–100 compared to KPS 10–60.

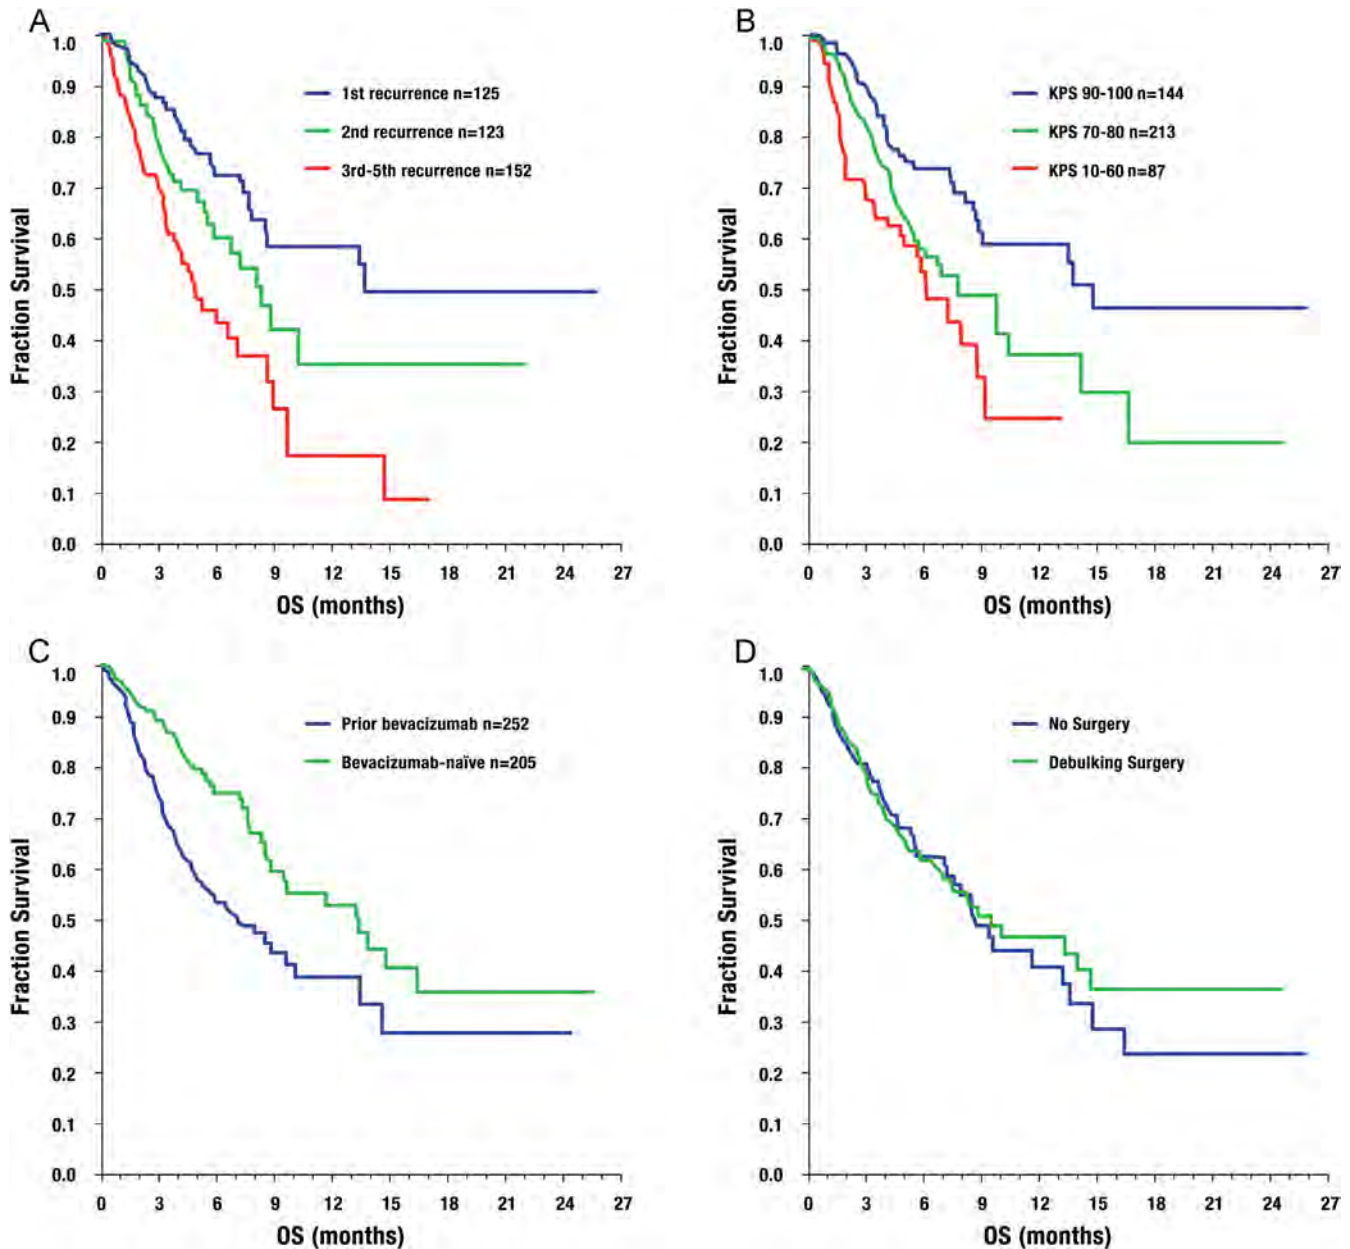

<75% or <18 hours daily). Kanner et al (see accompanying Kanner article in this supplement) recently reported similar findings when re-examining data from the EF-11 trial: median OS was significantly longer with a monthly compliance rate for NovoTTF Therapy ≥75% than <75% (7.7 v 4.5 months,  $P = .042$ ). The compliance findings from each of these studies are consistent with the mechanism of action of NovoTTF Therapy, which depends on almost continuous administration (≥18 hours per day) for a prolonged period of time (≥4 weeks).<sup>21,22</sup> However, patients in PRiDe who had suboptimal compliance were also found to have lower KPS and were, in general, at later stages of their disease. It is unclear whether they also may have had larger tumors or inadequate social support. Nevertheless, consistent with previous findings, our data suggest that applying NovoTTF Therapy to patients with higher performance status, earlier in their recurrence and ensuring treatment compliance, can maximize clinical benefit.

Additional analyses uncovered other prognostic factors that were important for patients in PRiDe. Of interest, in our subgroup analysis, 55.1% of patients in PRiDe who received prior bevacizumab therapy demonstrated a shorter median OS of 7.2 months, as compared to a median OS of 13.4 months in bevacizumab-naïve patients. The shorter survival in patients treated previously with bevacizumab may be a result of acquired tumor resistance and development of a more aggressive phenotype with

infiltrative tumor progression on MRI.<sup>9,10</sup> Moreover, patients with recurrent GBM tumors that progress while on bevacizumab therapy are typically resistant or refractory to subsequent cytotoxic chemotherapy,<sup>1,11,12</sup> and have a median OS of just 2.7 months. Therefore, the PRiDe data suggest that at least a percentage of bevacizumab-resistant tumors remain responsive to NovoTTF Therapy. Future analysis of responders and nonresponders to NovoTTF Therapy will need to include molecular genetic analysis of the tumor (and especially MGMT methylation status), the estimated tumor size (volume) as measured by fluid attenuated inversion recovery sequence on MRI, and more detailed analysis of the extent of resection.

Our analysis of KPS in PRiDe also demonstrated that higher KPS correlated with longer OS. It is unclear at this time whether or not patients who had KPS 90–100 had smaller tumors than the rest of the cohort or perhaps more extensive resections. KPS is often, but not always, a measure of tumor size, particularly the microscopic invasive component of the glioblastoma. Whether or not the median tumor size, as measured by gadolinium-enhanced T1-weighted and/or FLAIR MRI, differ between the subgroup with KPS 90–100 versus 70–90 and 10–60 remains to be determined. Of note, age was not a predictor of OS in the PRiDe dataset when evaluated either by direct correlation (Pearson correlation coefficient) or a

**Figure 4.** Kaplan-Meier overall survival (OS) curves for recurrent glioblastoma multiforme patients treated with NovoTTF Therapy in PRiDe based on (A) recurrence number, (B) Karnofsky performance status (KPS), (C) prior bevacizumab use, and (D) prior debulking surgery, respectively.

Cox proportional hazards model ( $P = .20$ ). In addition, age was not correlated with compliance in the PRiDe (correlation coefficient = 0.02;  $P = .37$ ). Taken in the context of the overall efficacy results, these findings suggest NovoTTF Therapy works well for patients of all ages and that advanced age is not associated with lower compliance. It would also be interesting to know if marital status (or other measures of patient support) influence compliance and survival, but data on marital status were not collected in PRiDe.

Finally, the PRiDe dataset did not capture patients on combination treatments in which additional

biologic therapy or chemotherapy were added to NovoTTF Therapy. It is possible that the longer survival seen in clinical practice with NovoTTF Therapy compared to NovoTTF monotherapy in the EF-11 trial is a reflection of combination use of NovoTTF Therapy with biological agents or cytotoxic chemotherapy. In fact, preclinical data have suggested that TTFields are additive or even synergistic with chemotherapies in cell culture.<sup>34-36</sup> Therefore, the potential benefits of combining NovoTTF Therapy with other systemic therapies warrant further investigation. A phase III trial of NovoTTF Therapy together with temozolomide

compared to temozolomide alone is currently ongoing in patients with newly diagnosed glioblastoma. The results of this trial will shed light on the possible additive or synergistic effects of NovoTTF Therapy and systemic chemotherapy.

In summary, PRiDe and the EF-11 trial represent one of the largest datasets of patients with recurrent GBM published to date, containing 700 patients in total, 567 of whom were treated with NovoTTF Therapy. The results, individually and collectively, provide further support for the use of NovoTTF Therapy to treat recurrent, supratentorial GBM. Observations from the post-marketing registry demonstrate that the safety and efficacy observed with NovoTTF Therapy in a clinical trial extend to the real-world, clinical practice setting. Future investigations may need to include NovoTTF Therapy in combination with other recurrent GBM treatments, which together may have additive or synergistic effects on patient outcomes.

# Long-term survival of patients suffering from glioblastoma multiforme treated with tumor-treating fields

Aaron Michael Rulseh<sup>1</sup>, Jiří Keller<sup>1,2</sup>, Jan Klener<sup>3</sup>, Jan Šroubek<sup>3</sup>, Vladimír Dbalý<sup>3</sup>, Martin Syřůček<sup>4</sup>, František Tovaryš<sup>3</sup> and Josef Vymazal<sup>1,5\*</sup>

## Abstract

Glioblastoma multiforme (GBM) is the most common and malignant primary intracranial tumor, and has a median survival of only 10 to 14 months with only 3 to 5% of patients surviving more than three years. Recurrence (RGBM) is nearly universal, and further decreases the median survival to only five to seven months with optimal therapy. Tumor-treating fields (TTField) therapy is a novel treatment technique that has recently received CE and FDA approval for the treatment of RGBM, and is based on the principle that low intensity, intermediate frequency electric fields (100 to 300 kHz) may induce apoptosis in specific cell types. Our center was the first to apply TTField treatment to histologically proven GBM in a small pilot study of 20 individuals in 2004 and 2005, and four of those original 20 patients are still alive today. We report two cases of GBM and two cases of RGBM treated by TTField therapy, all in good health and no longer receiving any treatment more than seven years after initiating TTField therapy, with no clinical or radiological evidence of recurrence.

**Keywords:** Glioblastoma multiforme, Recurrent glioblastoma multiforme, Tumor-treating fields, Long-term survival

## Background

Glioblastoma multiforme (GBM) is the most common and malignant primary intracranial tumor, representing as much as 30% of primary brain tumors with increasing incidence in some geographic regions [1]. Its incidence has been shown to increase with age [2]. Despite the introduction of aggressive treatment with temozolomide, the median survival time of adult patients remains approximately 10 months and as high as 14 months in patients receiving combined treatment with radiotherapy [3]. Only 3 to 5% of patients survive more than three years [4], and sporadic reports of survival exceeding five years are rare [5]. The exact clinical and molecular factors that contribute to such long-term survival are still unknown; however, younger age and a high Karnofsky performance scale (KPS) are considered prognostically favorable factors [4]. Recently, MGMT gene promoter

methylation and IDH1 mutation have been shown to correlate with longer survival as well [6]. Recurrence of GBM is nearly universal, and patients with recurrent glioblastoma multiforme (RGBM) fare even worse, with a median survival of only five to seven months with optimal therapy [7].

Tumor-treating fields (TTField) therapy is a novel treatment technique with the potential to treat various forms of cancer. TTField therapy is based on the principle that low intensity, intermediate frequency electric fields (100 to 300 kHz) have an anti-mitotic effect which acts during late metaphase and anaphase, with specific frequencies affecting specific cell types [8]. The applied fields disrupt mitotic spindle microtubule assembly and the segregation of intracellular organelles during cell division, leading to apoptosis [9]. TTField therapy has been tested in patients with advanced non-small cell lung cancer [10] and has recently received CE and FDA approval for the treatment of RGBM based on the results of a phase III clinical trial [11].

Our center was the first in the world to apply TTField treatment to histologically proven GBM patients in a

\* case in present report.

small pilot study of 20 individuals in 2004 and 2005 (Table 1). The inclusion criteria of the study included a KPS  $\geq 70\%$  and age  $\geq 18$  years, and the patients were divided into two groups. The first group consisted of 10 patients diagnosed with RGBM after failing temozolomide treatment that were treated with TTField therapy alone [9]. The second group consisted of 10 newly diagnosed GBM patients at least four weeks post radiation therapy (with adjuvant temozolomide) [12] that received TTField therapy combined with maintenance temozolomide. The treatment duration in individual patients varied between one and one and a half years, and all histological samples were independently examined in two laboratories in two countries. We report two cases of GBM and two cases of RGBM treated by TTField therapy, all in good health and no longer receiving any treatment more than seven years after initiating TTField treatment, with no clinical or radiological evidence of recurrence.

Baseline characteristics of all 20 participants in the original pilot study. Dates are presented as month/year for simplicity, age calculations were performed on exact dates.

GBM, glioblastoma multiforme (newly diagnosed); KPS, Karnofsky performance scale; L., left; No., number; R., right; RGBM, recurrent glioblastoma multiforme.

## Case presentation

### Case 1

A 52-year-old woman with a history of epileptic seizures and left-sided hemiparesis was diagnosed with an intra-axial brain tumor, suspected to be a high-grade glioma based on the magnetic resonance imaging (MRI) findings (Figure 1a). The tumor was resected with the help of functional blood oxygen level dependence (BOLD-fMRI) neuronavigation in April 2004. Gross total resection was performed and pathological analysis revealed clear evidence of glioblastoma. Standard radiotherapy (60 Gy) and chemotherapy with temozolomide followed. After radiotherapy and chemotherapy, a follow-up MRI in July 2004 showed two enhancing lesions that were highly suspected to be tumor recurrence (Figure 1b). TTField therapy was initiated in August 2004 as monotherapy. In September 2004, one month after starting TTField therapy, one of the enhancing lesions increased in size (Figure 1c); however, treatment with TTField therapy was continued since the progression was asymptomatic. By February 2005, both enhancing lesions had disappeared (Figure 1d) and are no longer detectable (Figure 1e). TTField treatment was discontinued after one year in August 2005, with no treatment administered after that time. The last MR examination from August 2011 shows no evidence of enhancing tumor.

**Figure 1 Serial MR imaging in Case 1.** T1-weighted image after application of contrast agent. **a)** April 2004, before surgery. GBM located in the right central region. **b)** July 2004, post-operative radiotherapy and chemotherapy. Two enhancing lesions present. **c)** September 2004, one month after the start of TTField therapy. The dorsal enhancing lesion increased in size, highly suspicious of tumor recurrence. **d)** June 2005, TTField treatment. No enhancing lesion present. **e)** August 2011. No enhancing lesion present. GBM, glioblastoma multiforme; MR, magnetic resonance; TTField, tumor-treating fields.

The patient has mild, residual left-sided hemiparesis, and otherwise feels completely healthy with no subjective complaints and a KPS of 90.

#### Case 2

A 41-year-old male presented with pronunciation difficulties in December 2003. Neurological examination revealed slight right-sided hemiparesis, and MRI revealed an intra-axial tumor suspected to be high-grade glioma (Figure 2a). Surgery was delayed due to intercurrent infection (influenza) until March 2004, and the tumor was then partially resected. Pathological analysis revealed histological characteristics of glioblastoma. Standard radiotherapy (60 Gy) and chemotherapy with temozolomide followed. A follow-up examination in August 2004 showed an enhancing lesion suspected to be a recurrent tumor (Figure 2b). TTField therapy was initiated in August 2004. By March 2005 the enhancing tumor had progressed and become cystic (Figure 2c). Again, treatment with TTField therapy was continued due to the asymptomatic nature of this progression. By October 2005 the tumor had regressed (Figure 2d) while the patient was still receiving TTField therapy. TTField therapy was discontinued in February 2006. A discrete, enhancing lesion is still present (last MRI in November 2011, Figure 2e). This small, enhancing lesion was examined with MR spectroscopy (Figure 2f) and showed noise-signal only, while the spectra in neighboring voxels were practically normal (Figure 2g). Positron emission tomography (PET) did not reveal any tumor-like patterns. The patient is in good health, has minor difficulties with speech, and is completely independent, with a KPS of 90 to 100.

#### Case 3

A 31-year-old male presented with an epileptic seizure in January 2005. MRI examination revealed a tumor in the right frontal lobe that was suspected to be a high grade glioma (Figure 3a). The tumor was totally resected

macroscopically (gross total resection) and showed clear histopathological characteristics of glioblastoma (World Health Organization (WHO) grade IV). Standard radiotherapy (60 Gy) and chemotherapy with temozolomide followed. TTField treatment was started in October 2005 concomitant to maintenance temozolomide and both treatments were discontinued in October 2006. Since that time, no tumor recurrence has been detected (Figure 3b). The patient is in good health, off all treatment and with a KPS of 100.

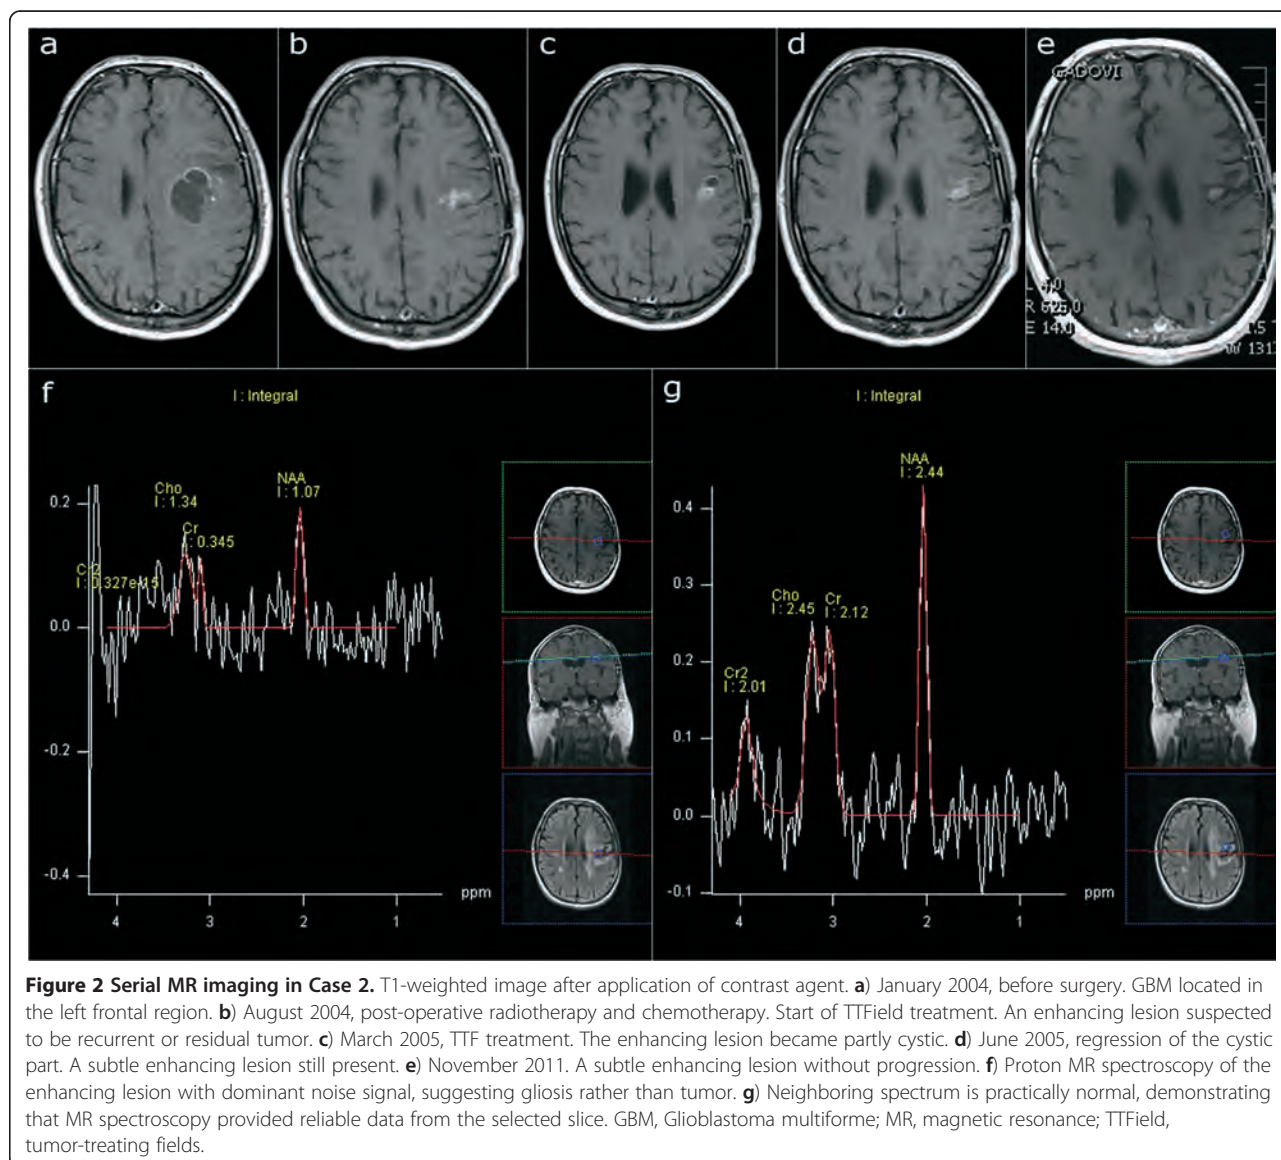

#### Case 4

A 33-year-old female underwent MRI of the brain following an epileptic seizure in November 2005. A tentative diagnosis of high-grade glioma was made based on MRI findings (Figure 4a). The tumor was completely resected macroscopically (gross total resection) in February 2006 and showed clear histopathological characteristics of glioblastoma (WHO grade IV). Standard radiotherapy (60 Gy) and chemotherapy with temozolomide followed. No recurrence was noted on follow-up MRI in February 2007 (Figure 4b). TTField treatment was started in April 2006 concomitant to maintenance temozolomide and both treatments were discontinued in April 2007. No tumor recurrence has been detected on a number of follow-up MRI examinations (Figure 4c), the last of which was performed in September 2011. MR spectroscopy in a small volume of tissue with corresponding increased signal intensity on Fluid Attenuated Inversion Recovery (FLAIR) images did not show a tumor-like pattern (Figure 4d). Currently the patient is off all treatment, in good health, with a KPS of 100.

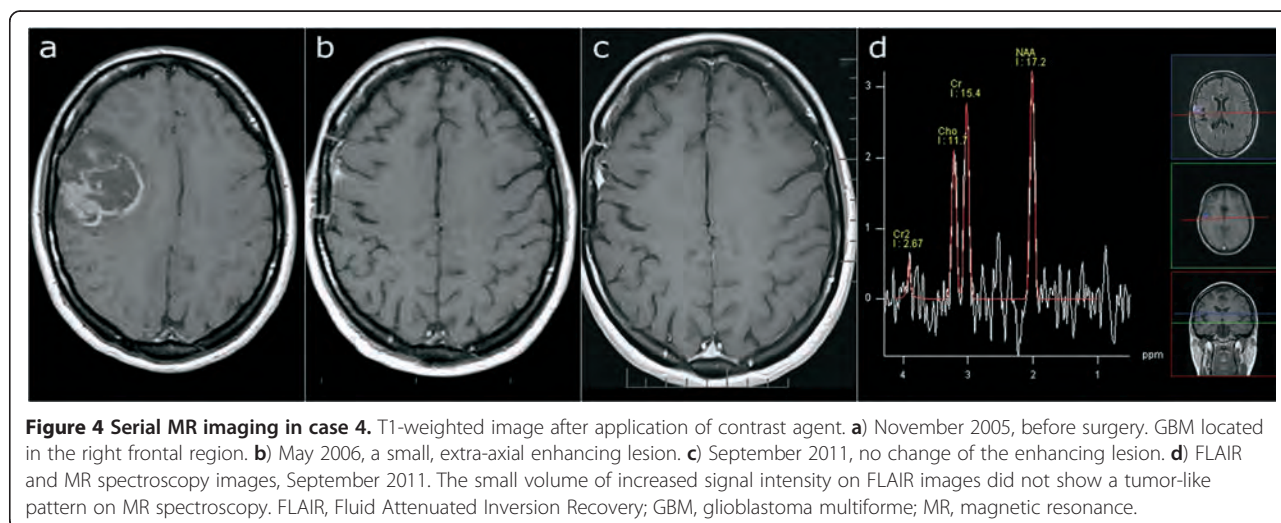

#### Discussion

Despite multi-modal treatment, the prognosis of GBM remains poor. Recurrence is likely inevitable provided the patient survives long enough, and further reduces the median survival to only five to seven months [4,7]. There have been documented cases of GBM patients

surviving longer than three years, termed long-term survival (LTS), representing approximately three to five percent of GBM patients [4]. Survival of GBM patients longer than five years, however, is exceptional, representing as few as 0.5% of patients [5].

Twenty percent of the participants in our pilot study (4 out of 20) have survived until the time of this report, roughly seven years (Figure 5). These individuals continue to undergo regular neurological and radiological examinations, and do not show any signs of recurrence. The data from standard MR imaging are further supported by MR spectroscopy that does not show any

tumor-like patterns in regions with corresponding abnormal signal intensity.

Younger age and a higher KPS have been proposed as prognostically favorable parameters for longer survival [4]. The mean age of our LTS-RGBM patients (Cases 1 and 2) was 47.5 years compared to 51.5 years for the rest of the RGBM group [9]. This difference is not striking. Although we cannot completely exclude pseudo-progression or radiation necrosis in these patients diagnosed without histological verification of the recurrent lesion, their continued survival is still remarkable. In the group of newly diagnosed GBM, the mean age of LTS-GBM patients (Cases 3 and 4) was 32 years compared to 51 years for the rest of the group. This was likely a contributing factor to their long term survival; however, this does not explain seven years of disease-free survival. All of the patients in the trial had a KPS  $\geq 70$  and the median KPS was 80.

TTField therapy has been shown to effectively inhibit glioma cell replication *in vitro* and *in vivo* [8,9]. The published results of the pilot trial using TTField therapy in GBM patients were extremely promising and served as the basis for a phase III clinical trial comparing TTField therapy to the best available active chemotherapy in patients with RGBM [11]. The phase III trial showed that patients with RGBM had comparable overall survival to those receiving chemotherapy without the side effects of chemotherapy and with a better quality of life. In the present study, no serious, probable, treatment-related adverse events occurred, with only contact dermatitis treated by topical corticosteroid documented in 17 of 20 patients. In the phase III trial, 8% of TTField therapy patients survived for longer than three years [11]. The reasons for the smaller number of long term survival patients in the phase III trial compared to the pilot trial is likely related to the younger age of the

patients presented in this report, the fact that they were at their first recurrence after temozolomide (versus second to third recurrence in the phase III trial) and, most importantly, continued TTField therapy for many months, despite initial growth of the contrast enhancing lesion while on therapy. Thus, we suggest that in order to increase the probability of response to TTField therapy and subsequent long term survival, TTField treatment should be continued even in the face of initial radiologic tumor growth.

## Conclusions

In the present paper we report two cases of GBM and two cases of RGBM treated by TTField therapy, all in good health and no longer receiving any treatment more than seven years after initiating TTField therapy, with no clinical or radiological evidence of recurrence. Our results indicate that TTField treatment may be remarkably successful in a subgroup of GBM/RGBM patients, and further investigation is needed to identify any unique characteristics of this patient group.

## Consent

Written informed consent was obtained from all patients for publication of this case report and any accompanying images. A copy of the written consent is available for review by the Editor-in-Chief of this journal.

**IMPORTANCE** Glioblastoma is the most devastating primary malignancy of the central nervous system in adults. Most patients die within 1 to 2 years of diagnosis. Tumor-treating fields (TTFields) are a locoregionally delivered antimitotic treatment that interferes with cell division and organelle assembly.

**OBJECTIVE** To evaluate the efficacy and safety of TTFields used in combination with temozolomide maintenance treatment after chemoradiation therapy for patients with glioblastoma.

**DESIGN, SETTING, AND PARTICIPANTS** After completion of chemoradiotherapy, patients with glioblastoma were randomized (2:1) to receive maintenance treatment with either TTFields plus temozolomide (n = 466) or temozolomide alone (n = 229) (median time from diagnosis to randomization, 3.8 months in both groups). The study enrolled 695 of the planned 700 patients between July 2009 and November 2014 at 83 centers in the United States, Canada, Europe, Israel, and South Korea. The trial was terminated based on the results of this planned interim analysis.

**INTERVENTIONS** Treatment with TTFields was delivered continuously (>18 hours/day) via 4 transducer arrays placed on the shaved scalp and connected to a portable medical device. Temozolomide (150-200 mg/m<sup>2</sup>/d) was given for 5 days of each 28-day cycle.

**MAIN OUTCOMES AND MEASURES** The primary end point was progression-free survival in the intent-to-treat population (significance threshold of .01) with overall survival in the per-protocol population (n = 280) as a powered secondary end point (significance threshold of .006). This prespecified interim analysis was to be conducted on the first 315 patients after at least 18 months of follow-up.

**RESULTS** The interim analysis included 210 patients randomized to TTFields plus temozolomide and 105 randomized to temozolomide alone, and was conducted at a median follow-up of 38 months (range, 18-60 months). Median progression-free survival in the intent-to-treat population was 7.1 months (95% CI, 5.9-8.2 months) in the TTFields plus temozolomide group and 4.0 months (95% CI, 3.3-5.2 months) in the temozolomide alone group (hazard ratio [HR], 0.62 [98.7% CI, 0.43-0.89]; P = .001). Median overall survival in the per-protocol population was 20.5 months (95% CI, 16.7-25.0 months) in the TTFields plus temozolomide group (n = 196) and 15.6 months (95% CI, 13.3-19.1 months) in the temozolomide alone group (n = 84) (HR, 0.64 [99.4% CI, 0.42-0.98]; P = .004).

**CONCLUSIONS AND RELEVANCE** In this interim analysis of 315 patients with glioblastoma who had completed standard chemoradiation therapy, adding TTFields to maintenance temozolomide chemotherapy significantly prolonged progression-free and overall survival.

**TRIAL REGISTRATION** clinicaltrials.gov Identifier: NCT00916409

**G**lioblastoma is the most devastating primary malignancy of the central nervous system in adults. Standard treatment consists of maximal safe surgical resection or a diagnostic biopsy, followed by radiotherapy (60 Gy) with concomitant daily temozolomide chemotherapy, and then maintenance treatment with temozolomide for 6 to 12 months.<sup>1</sup> However, most patients will die within 1 to 2 years. Median progression-free survival from diagnosis of 6.2 to 7.5 months and median overall survival from diagnosis of 14.6 to 16.7 months have been reported in clinical trials.<sup>1-4</sup> The reported 2- and 5-year survival rates<sup>5</sup> are 27% and 10%, respectively. During the last decade, all attempts to improve the outcome for patients with glioblastoma have failed when evaluated in large randomized trials.<sup>2-4,6,7</sup>

Tumor-treating fields (TTFields) are an antimitotic treatment that selectively disrupts the division of cells by delivering low-intensity, intermediate-frequency (200 kHz) alternating electric fields via transducer arrays applied to the shaved scalp.<sup>8-10</sup> In preclinical models, TTFields have been shown to cause mitotic arrest and apoptosis by disrupting mitotic spindle formation during metaphase and causing dielectrophoretic movement of polar molecules during cytokinesis.<sup>8,10-12</sup> In a randomized phase 3 trial in which TTFields were compared with chemotherapy in 237 patients with recurrent glioblastoma, the use of TTFields did not prolong progression-free survival or overall survival, but the therapy was associated with better quality of life without the typical chemotherapy-associated toxic effects.<sup>13</sup>

Based on preclinical data demonstrating a synergistic antitumor effect with chemotherapy and TTFields, and pilot clinical feasibility data in combination with temozolomide,<sup>9</sup> we initiated this phase 3 trial. The objective was to evaluate the efficacy and safety of TTFields used in combination with maintenance temozolomide in patients with glioblastoma after initial treatment with temozolomide and radiotherapy.

## Methods

### Study Population

Patients eligible for this study (1) had histologically confirmed supratentorial glioblastoma (World Health Organization grade IV astrocytoma<sup>14</sup>), (2) were progression-free after having undergone maximal safe debulking surgery when feasible or biopsy, and (3) had completed standard concomitant chemoradiotherapy with temozolomide. Other eligibility criteria were (1) age of 18 years or older, (2) Karnofsky Performance Status (KPS) score of 70% or higher (the KPS score describes the general condition of a patient; a KPS score  $\geq 70\%$  ensures some independence in activities of daily living), and (3) adequate bone marrow, liver, and renal function.

Prior use of implanted carmustine wafers was allowed. Patients with infratentorial tumor location and severe comorbidities were excluded. All patients provided written informed consent before entering the study; the study was approved by the institutional review boards or ethics committees of all 83 participating centers. The trial protocol appears in Supplement 1.

### Study Design and Treatment

This multicenter, open-label, randomized phase 3 trial was designed to test the efficacy and safety of TTFields in combination with temozolomide for treatment of glioblastoma after initial treatment with chemoradiation. After the completion of treatment with temozolomide and radiotherapy, patients were randomized at a ratio of 2 to 1 (Figure 1) to receive standard maintenance temozolomide chemotherapy (150-200 mg/m<sup>2</sup>/d for 5 days every 28 days for 6-12 cycles according to the protocol<sup>1</sup> from the European Organisation for Research and Treatment of Cancer Brain Tumor and Radiotherapy Groups and the National Cancer Institute of Canada Clinical Trials Group) with or without the addition of TTFields. Treatment with TTFields was to be initiated within 4 to 7 weeks from the last dose of concomitant temozolomide and radiotherapy. Randomization was performed through a central web-based randomization system and was stratified by extent of resection (biopsy, partial resection, gross total resection) and by O<sup>6</sup>-methylguanine-DNA methyltransferase (*MGMT*) methylation status (methylated, unmethylated, or unknown).

For patients with available paraffin-embedded tumor tissue, evaluation of *MGMT* gene promoter methylation status was performed as described previously<sup>7,15,16</sup> by a central laboratory blinded to treatment group (MDxHealth). If *MGMT* methylation status could not be determined centrally prior to randomization, local *MGMT* methylation status was used for stratification.

Patients in the TTFields plus temozolomide group received continuous TTFields combined with standard maintenance temozolomide. Patients receiving TTFields had 4 transducer arrays placed on the shaved scalp and connected to a portable device set to generate 200-kHz electric fields within the brain (Optune, Novocure Ltd). Transducer array layouts were determined using a mapping software system for TTFields to optimize field intensity within the treated tumor (NovoTAL, Novocure Ltd). After being trained to operate the device, the patient continued treatment at home. The transducer arrays were supplied in sterile packaging and replaced by the patient, a caregiver, or a device technician twice per week. Although uninterrupted treatment was recommended, short treatment breaks for personal needs were allowed.

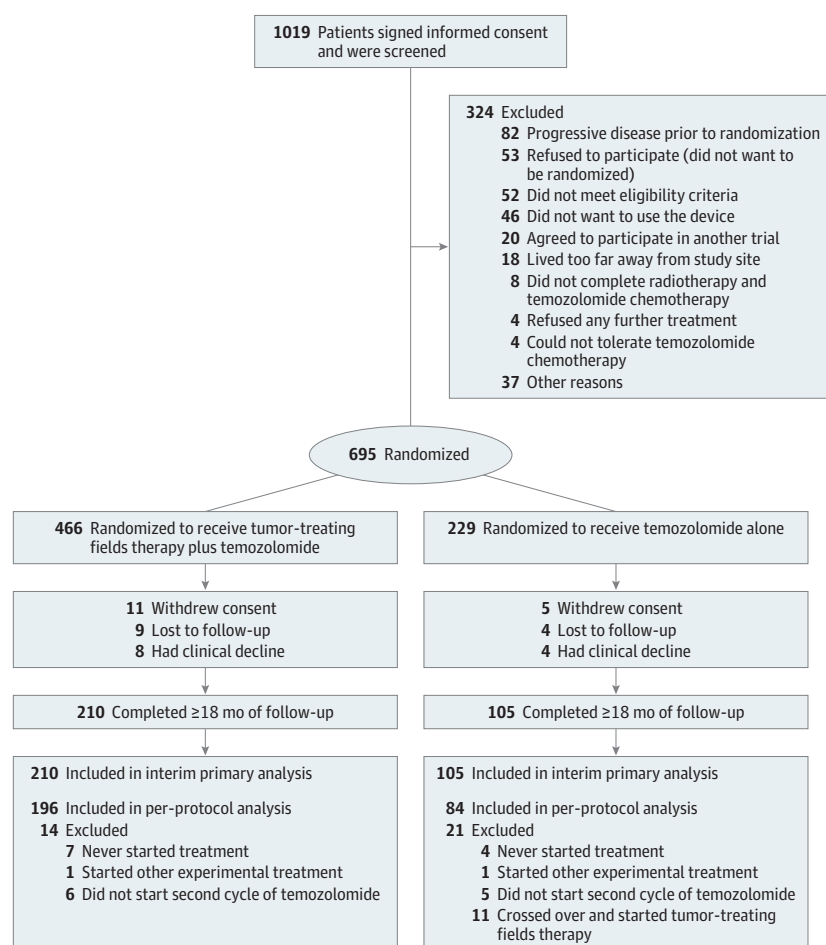

If a patient experienced tumor progression, second-line chemotherapy was offered per local practice. However, in the TTFields plus temozolomide group, TTFields could be continued until the second radiological progression, or clinical deterioration, for a maximum of 24 months.

### Patient Surveillance and Follow-up

Baseline contrast-enhanced magnetic resonance imaging (MRI) of the brain was required within 2 weeks before starting treatment with maintenance temozolomide with or without TTFields. A complete physical examination with collection of laboratory parameters was performed within 1 week of treatment initiation. The evaluation also included a quality-of-life questionnaire (QLQ-C30) that has a brain-specific module (BN-20), which was developed by the European Organisation

Figure 1. Recruitment and Inclusion of Patients in the Study

for Research and Treatment of Cancer Brain Tumor and Radiotherapy Groups.<sup>17,18</sup> A Mini-Mental State Examination (a short bedside test used to evaluate cognition and memory) also was administered (a test result of 27-30 points is considered normal function).

Patients were seen monthly for medical follow-up and routine laboratory examinations. Quality of life was assessed every 3 months. Magnetic resonance imaging was to be performed every second month after the baseline MRI until second radiological progression in all patients. In the event of clinical progression, MRI was to be performed within 1 week after the study investigator became aware of it. All MRIs were reviewed centrally by 2 blinded independent radiologists (BioClinica Inc) and were evaluated for tumor response and progression using the criteria developed by Macdonald et al.<sup>19</sup> In cases in which the central reviewers were not in agreement, a third blinded radiologist adjudicated between them. The third radiologist was involved in 17% of the cases in the TTFields plus temozolomide group and in 18% of the cases in the temozolomide alone group.

The results of the central review were not communicated to the study investigator, and all treatment decisions were based on local imaging interpretation. Eight patients in the

TTFields plus temozolomide group (4%) compared with 6 patients in the temozolomide alone group (3%) were considered stable by blinded central review; however, treatment had been changed by the study investigator due to local interpretation of tumor progression. Patients were removed from the progression-free survival analysis at the date of treatment change when this occurred before evidence of tumor progression or when patients reached the cutoff date without tumor progression.

Adverse events were recorded prospectively according to the National Cancer Institute's Common Terminology Criteria (version 3.0) until 2 months after treatment discontinuation. Adverse events are presented descriptively as number and percentage of patients with each adverse event term for all patients available at the time of the interim analysis. Treatment adherence with TTFields was recorded electronically by the device as average daily use in hours per day and information was reviewed and transferred at the monthly follow-up visit.

### Statistical Considerations

The primary end point was progression-free survival in the intent-to-treat (ITT) population assessed by an independent review panel (80% power; hazard ratio [HR], 0.78; 2-sided  $\alpha$  level

of .05). The study was also designed to have 80% power (HR, 0.76; 2-sided a level of .05) to examine overall survival as a secondary end point. To avoid an increase in the risk of a false-positive result, overall survival was to be tested statistically only if the primary end point was met.

This prespecified interim analysis was to be performed after the first 315 randomized patients reached a minimum 18-month follow-up. The final type I error rate of 0.05 was split between the interim and final analyses based on a standard a spending function.<sup>20-22</sup> The protocol prespecified that overall survival would be analyzed in an as-treated population, excluding all patients in both treatment groups who (1) never started maintenance temozolomide, (2) had major protocol violations, (3) crossed over to the other treatment group, or (4) received TTFields outside the protocol setting.

The primary end point would be achieved in the interim analysis if progression-free survival in the ITT population was significantly longer in the intervention group compared with the control group using a stratified log-rank test with an a level of .01. The secondary end point would be achieved in the interim analysis if overall survival in the as-treated population (per-protocol population) was significantly longer in the TTFields plus temozolomide group using a stratified log-rank test with an a level of .006. The confidence intervals that go with the HRs are presented as 1 minus the prespecified a level for each analysis. For example, the a level in the per-protocol interim analysis for overall survival was .006. Therefore, the corresponding confidence interval used for presenting the HRs was 1.000 – 0.006 (99.4% confidence interval). An upper confidence limit of less than 1 indicates the prespecified statistical threshold was met. An independent data and safety monitoring committee was chartered to stop the trial if the interim analysis of progression-free survival (ITT population) and overall survival (per-protocol population) surpassed these predetermined thresholds, as well as for futility or safety concerns.

In addition to these prespecified analyses, an analysis of overall survival in the ITT population was performed. Furthermore, a robustness analysis including all 695 patients enrolled in the trial served to validate the findings of the interim analysis (database lock: December 29, 2014; eAppendix 1 in Supplement 2).

Multiple imputation analyses also were performed for the trial's primary end point of progression-free survival in the ITT population to test the sensitivity of the results to possible bias using informative and interval censoring. These analyses included (1) treating all patients with informative censoring as treatment failures in the TTFields plus temozolomide group, (2) censoring all patients with informative censoring in the temozolomide alone group (worst case scenario), and (3) treating all events in the TTFields plus temozolomide group and in the temozolomide alone group as occurring differentially at different periods during the inter-MRI interval before the date of tumor progression.

All statistical analyses were performed using SAS version 9.4 (SAS Institute Inc) and R version 3.1.1.<sup>23</sup> The final analysis will be performed when all 695 patients enrolled in the study have at least 18 months of follow-up and will include prespeci-

fied subgroup analyses and additional secondary end points, including quality of life.

## Results

### Study Participants

Between July 2009 and November 2014, there were 695 patients with newly diagnosed glioblastoma randomized to receive either TTFields plus temozolomide (n = 466) or temozolomide alone (n = 229). Data for the interim analysis included 210 patients randomized to TTFields plus temozolomide and 105 to temozolomide alone (Figure 1; database lock: September 5, 2014). The independent data and safety monitoring committee met in October 2014 to review the interim analysis; the trial met the predefined boundaries for success (improvement of both progression-free and overall survival) and the committee recommended study termination, thus allowing patients in the control group to crossover and receive TTFields.

After approval of study termination by the US Food and Drug Administration, the trial was closed to recruitment on November 29, 2014, after 695 patients of the planned 700 patients had already been randomized. All patients in the control group with ongoing maintenance therapy were offered to receive TTFields. At the time of this report, 35 patients in the control group crossed over to receive TTFields. Follow-up for all patients continues according to the protocol.

Patient baseline characteristics were well balanced between the 2 groups (Table 1). The median age was 57 years and 66% were male. The median KPS score was 90%. Sixty-four percent of patients had a gross total resection and 11% had only a diagnostic biopsy. Tumor tissue for central *MGMT* testing was available for 72% of the patients; the *MGMT* methylation frequency was 39% (75/191 valid tests; 39% for the TTFields plus temozolomide group and 41% for the temozolomide alone group). Tumor location in the brain was also comparable.

Carmustine wafers (Gliadel) were used at initial surgery in 2.4% of patients in the TTFields plus temozolomide group vs 2.9% of patients in the temozolomide alone group. Ninety-five percent of the patients were white and 61% were treated in the United States. The rest of the patients were treated at centers in Canada, Europe, Israel, and South Korea. The median time from diagnosis to randomization was 3.8 months (range, 2.0-5.7 months) for patients in the TTFields plus temozolomide group and 3.8 months (range, 1.4-5.7 months) for those in the temozolomide alone group. The median time from the end of treatment with temozolomide and radiotherapy to randomization was 36 days in the TTFields plus temozolomide group and 38 days in the temozolomide alone group; 53% of patients were randomized after having started the first cycle of maintenance temozolomide. The median time from randomization to initiation of TTFields was 5 days.

### Treatment Delivery

All patients had completed radiotherapy and concomitant temozolomide as per local practice. The median number of temozolomide cycles until evidence of first tumor progression was 6 cycles (range, 1-26 cycles) for patients in the TTFields

<sup>b</sup> A higher score indicates better cognitive capability.

plus temozolomide group and 4.0 cycles (range, 1-24 cycles) for patients in the temozolomide alone group; the median duration of treatment with TTFields was 9 months (range, 1-58 months). Two-thirds (n = 141) of patients in the TTFields plus temozolomide group continued treatment with TTFields after first tumor progression. Three-quarters (n = 157) of patients receiving treatment with TTFields were adherent to therapy (ie, wearing the device >18 hours per day on average during the first 3 treatment months).

### Efficacy End Points

As prespecified, the primary end point for the efficacy results was based on progression-free survival in the ITT population of the interim analysis data set. After a median follow-up of 38 months (range, 18-60 months), the median progression-free survival from randomization was 7.1 months (95% CI, 5.9-8.2 months) in the TTFields plus temozolomide group compared with 4.0 months (95% CI, 3.3-5.2 months) in the temozolomide alone group (HR, 0.62 [98.7% CI, 0.43-0.89];

Figure 2. Survival Curves for Patients Included in the Interim Analysis in the Intent-to-Treat Population

stratified log-rank  $P = .001$ ; **Figure 2A**). Thus, adding TTFields to temozolomide treatment increased median progression-free survival in the ITT population by 3.1 months.

As per the statistical analysis plan, overall survival was to be tested in a prespecified per-protocol population only after the primary end point was found to surpass the threshold for significance in the interim analysis. Median overall survival in the per-protocol population was 20.5 months (95% CI, 16.7-25.0 months) in the TTFields plus temozolomide group ( $n = 196$ ) compared with 15.6 months (95% CI, 13.3-19.1 months) in the temozolomide alone group ( $n = 84$ ) (HR, 0.64 [95% CI, 0.42-0.98]; stratified log-rank  $P = .004$ ). The details on the per-protocol population and analyses are summarized in eAppendix 2 in Supplement 2.

In additional analyses in the ITT population, the median overall survival was 19.6 months (95% CI, 16.6-24.4 months) in the TTFields plus temozolomide group compared with 16.6 months (95% CI, 13.6-19.2 months) in the temozolomide alone group (HR, 0.74 [95% CI, 0.56-0.98]; stratified log-rank  $P = .03$ ; **Figure 2B**). The percentage of patients alive at 2 years following enrollment was 43% in the TTFields plus temozolomide group and 29% in the temozolomide alone group ( $P = .006$ ).

To assess the robustness of the interim analysis findings, additional analyses on all 695 patients randomized were performed. Patient characteristics of all patients randomized did not differ significantly from the interim data set, and the results for the main end points were similar in these analyses compared with the interim analysis (eAppendix 1 in Supplement 2).

Second-line treatments, such as nitrosoureas, temozolomide rechallenge, and bevacizumab, were received by 67% of the patients in the TTFields plus temozolomide group compared with 57% in the temozolomide alone group; about 40% of second-line therapies included bevacizumab and about 40% included nitrosoureas. The type of chemotherapy used at recurrence was balanced between treatment groups.

Secondary imputation analyses of progression-free survival with relation to the effects of interval and informational censoring did not change the conclusions of the primary progression-free survival analysis (eAppendix 3 in Supplement 2).

### Safety and Tolerability

The addition of TTFields to temozolomide therapy in patients with newly diagnosed glioblastoma was not associated with any significant increase in systemic toxic effects compared with temozolomide therapy alone (**Table 2**). The overall incidence, distribution, and severity of adverse events were similar in patients treated with TTFields plus temozolomide and in those treated with temozolomide alone. The only notable exception was a higher incidence rate of localized skin toxicity (medical device site reaction beneath the transducer arrays) in patients treated with TTFields plus temozolomide. Mild to moderate skin irritation was observed in 43% of patients treated with TTFields plus temozolomide and severe skin reaction (grade 3) in 2%. Mild anxiety, confusion, insomnia, and headaches were reported more frequently in the patients treated with TTFields plus temozolomide and occurred mainly at the time of therapy initiation. The incidence of seizures was almost identical in the 2 groups (15 [7%] in the TTFields plus temozolomide group vs 8 [8%] in temozolomide alone group). A total of 12 patients died of causes considered unrelated to treatment while receiving adjuvant therapy (8 [3.9%] in the temozolomide plus TTFields group and 4 [4.0%] in the temozolomide alone group; **Table 2**).

### Discussion

Glioblastoma is a highly aggressive brain tumor affecting men and women, frequently at the peak of life. Prognosis remains poor with no major treatment advance in more than a decade. In the interim analysis of this randomized clinical trial,

the addition of TTFields to standard maintenance temozolomide significantly improved progression-free and overall survival. The prespecified analyses revealed that patients randomized to receive TTFields plus temozolomide compared with patients randomized to receive temozolomide alone had a median progression-free survival of 7.1 months vs 4.0 months (ITT analyses). Patients who received TTFields plus temozolomide had a median overall survival of 20.5 months compared with 15.6 months in those who received temozolomide alone (as per the prespecified per-protocol analysis; the ITT analysis did not differ substantially).

Based on the results of this planned interim analysis, the trial's independent data and safety monitoring committee recommended termination of the trial. Because almost all patients had been enrolled (695/700) in the study by the time the recommendation was implemented, the full trial population will be followed up for both progression-free and overall survival. Subsequent analyses of all secondary end points and subgroups will be performed when the follow-up data are available.

The trial population and the results in the control group in this study were comparable with other glioblastoma clinical trials. Nevertheless, patients in this trial were randomized only after the end of radiochemotherapy, and for most, the first cycle of maintenance temozolomide had been started at the time of randomization; thus, patients with early tumor progression during radiochemotherapy were excluded. Most glioblastoma trials have reported survival from the date of initial diagnosis or study enrollment before starting radiochemotherapy, thus 3 to 4 months before randomization of the current study.

When the interval from diagnosis to randomization is added to the outcome results in this study, the progression-free survival of 7.8 months in the control group is comparable with most other reported studies, and supports the generalizability of these results. The Radiation Therapy Oncology Group (RTOG) 0525 protocol randomized patients only after the end of treatment with temozolomide and radiotherapy, similar to our study.<sup>3</sup> The control groups with standard dose temozolomide only in these 2 trials were comparable: progression-free survival from randomization of 4.0 months in the present study and 5.5 months in the RTOG 0525 trial and overall survival of 16.6 months in both trials. Thus, the benefit observed with TTFields cannot be simply attributed to patient selection. In the present trial, the gain of 3 months in both median progression-free survival (from 4.0 months to 7.2 months; HR, 0.62) and median overall survival (from 16.6 months to 19.6 months; HR, 0.74), translating into a survival gain at 2 years of 14% (from 29% to 43%) in the ITT population is in the range of benefit that is considered clinically meaningful for therapeutic agents in oncology.

The prespecified analysis for overall survival in the interim analysis was to be based on the per-protocol population (n = 280); ie, removal in both study groups of the patients who did not start their second course of maintenance temozolomide or had major protocol violations. This analysis met the prespecified threshold for efficacy in the interim analysis for the per-protocol population. In a more conserva-

<sup>d</sup> Patients may have had more than 1 adverse event so subcategories do not total and not all events are subcategorized.

tive analysis using the ITT population, an overall survival benefit was also manifest. Furthermore, an analysis of robustness performed on all randomized patients enrolled at the time

of study termination (eAppendix 1 in Supplement 2) supports the conclusions of the interim analysis.

This clinical trial has some important limitations. Patient enrollment occurred only after the end of radiochemotherapy, leading to some variation in the delivery of standard treatment of temozolomide and radiotherapy. Patients who had progressed early during radiochemotherapy were not eligible for randomization, thus excluding patients with very poor prognoses. There is likely reporting bias for second-line therapies after tumor progression because in the TTFields plus temozolomide group, TTFields were to be continued, and thus, more detailed treatment information has been tracked for this group.

This analysis reports a planned interim analysis on data from the first 315 patients with at least 18 months of follow-up; however, for detailed and meaningful subgroup analyses, the mature data of the full data set will be needed. Treatment failure patterns, effects of second-line therapies, and additional molecular analyses on baseline tumor biopsies will allow for better understanding of the clinical effects of this novel treatment modality. With the last patient randomized on November 29, 2014, however, these data are not expected before the end of 2016.

This was an open-labeled study. A sham or placebo treatment for the control group was considered neither practical (patients would be able to sense heat when they were receiving TTFields) nor appropriate (due to the burden for patients and caregivers and the need to shave the scalp and have transducer arrays placed). In this respect, the trial resembles studies evaluating radiation therapy. This raises the question of a placebo effect leading to the improved outcome. Although some effect of placebo may be expected on subjective end points, such as cognitive function and quality of life, objective end points, such as overall and progression-free survival (assessed by a blinded review panel), are independent of pla-

cebo effects in cancer therapy.<sup>24</sup> The panel did not have information on treatment received and no stigmata of TTFields array pads were evident on MRI.

Recent randomized studies of patients with glioblastoma, which did not use placebo controls, failed to show any increase in progression-free or overall survival<sup>3,7</sup> despite intensive treatment regimens requiring twice weekly hospital visits.<sup>7</sup> The magnitude of effect size seen in the present trial (HR of 0.62 for progression-free survival and 0.74 for overall survival) is beyond what could be attributed to a placebo effect. In addition, the support provided to patients in the TTFields plus temozolomide group by device support specialists during the trial was largely technical in nature and did not include medical supportive care. Medical follow-up with monthly visits was the same for both treatment groups.

Because TTFields were applied only to the head, an increase in systemic adverse events was neither seen nor expected. No increase in seizure rate or neurological adverse events was observed. Almost half of the patients treated with TTFields did experience some grade 1 to 2 (mild to moderate) localized skin reaction related to the application of the transducer arrays used to deliver the TTFields. This adverse effect could be managed using published skin care guidelines for patients receiving TTFields.<sup>25</sup> Only 2% of patients receiving TTFields had grade 3 to 4 (severe) skin reactions beneath the transducer arrays.

## Conclusions

In this interim analysis of 315 patients with glioblastoma who had completed standard chemoradiation therapy, adding TTFields to maintenance temozolomide chemotherapy significantly prolonged progression-free and overall survival.

**Author Contributions:** Drs Stupp and Ram had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

**Study concept and design:** Stupp, Kirson, Weinberg, Palti, Ram.

**Acquisition, analysis, or interpretation of data:** All authors.

**Drafting of the manuscript:** Stupp, Kirson, Ram.

**Critical revision of the manuscript for important intellectual content:** All authors.

**Statistical analysis:** Steinberg.

**Obtained funding:** Palti.

**Administrative, technical, or material support:**

Stupp, Kirson, Weinberg, Hegi, Ram.

**Study supervision:** Stupp, Kirson, Weinberg, Hegi, Ram.

**Conflict of Interest Disclosures:** The authors have completed and submitted the ICMJE Form for

Disclosure of Potential Conflicts of Interest. Dr Stupp reported receiving travel assistance from Novocure for data review and presentation of the results at medical meetings; and receiving personal fees for serving on advisory boards for Roche/Genentech, Merck KGaA, Merck & Co, and Novartis. Dr Taillibert reported receiving personal fees from Mundipharma EDO and Roche. Dr Kanner reported receiving institutional grant funding and personal fees for speaking and device training from Novocure. Dr Kesari reported receiving institutional grant funding and personal fees for consulting and attending advisory meetings from Novocure. Dr Steinberg reported receiving consulting fees from Novocure for performing the statistical analysis. Dr Toms reported receiving personal fees from Novocure for serving on an advisory board. Dr Lieberman reported receiving institutional grant funding from Novocure. Dr Fink reported receiving personal fees from Novocure for serving on an advisory board; and receiving personal fees from Genentech for serving in the speakers program. Dr Zhu reported receiving institutional grant funding and personal fees from Novocure. Dr Engelhard reported receiving institutional grant funding and personal fees from Novocure. Dr Chen reported receiving grant funding, personal fees, nonfinancial support, and being a stock holder and chief

oncology officer in Pharmo-kinesis; and receiving grant funding, personal fees, nonfinancial support, and being a stock holder in and CEO of NeOnc Technologies. Dr David Tran reported receiving grant funding from Celldex, NWBiotech, Novocure, and Merck; and receiving personal fees from Novocure and prIme Oncology. Dr Hottinger reported receiving travel reimbursement and speakers fees from Novocure and Merck Sharp & Dohme; and receiving personal fees for serving on an advisory board for Roche. Dr Landolfi reported receiving personal fees from Novocure for serving on an advisory board. Dr Honnorat reported receiving trial support from Novocure and serving on an advisory board for Novocure. Dr Idbaih reported receiving grants from Fondation ARC pour la recherche sur le Cancer; receiving research support from IntselChimos and Beta-Innov; receiving personal fees from Novartis for attending a conference; receiving travel reimbursement from Hoffmann-La Roche; and serving as an editorial advisory board member for *Lettre du Cancérologue*. Drs Kirson, Weinberg, and Palti reported being employees of Novocure. Dr Palti also reported holding 35 issued US patents and minority stock ownership in Novocure. Dr Hegi reported receiving institutional grant funding from Novocure, Merck Sharp & Dohme, Roche, and Merck-Serono; and nonfinancial support from MDxHealth for sample testing. Dr Ram reported receiving institutional grant funding from Novocure; and serving as a paid consultant for and holding stock options in Novocure. Drs Taylor, Silvani, Barnett, Henson, Sroubek, Nam Tran, Desai, Caroli, and Kew reported having no disclosures.

**Funding/Support:** The study was funded by Novocure Ltd.

**Role of the Funder/Sponsor:** Novocure Ltd had a role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication. The study was designed by the first and last authors (R.S. and Z.R.), together with representatives from Novocure (mainly E.D.K.). The study oversight was supported and monitored by a clinical research organization (CRO), who also holds the database. Data were collected by the investigators and monitored by the CRO. Device use data were downloaded monthly and transferred to the study investigators or their research staff by device support specialists from Novocure Ltd. The data were analyzed separately by the statistician of the independent data monitoring committee and the study statistician (D.M.S.). Data interpretation was the responsibility of the first and last authors (R.S. and Z.R.), together with the study sponsor representative and project lead (E.D.K.). These 3 physicians also jointly developed the first draft. A subsequent mature draft and a prefinal version were circulated among all authors who gave additional input, contributed to, and approved the manuscript. The first and last authors (R.S. and Z.R.) and E.D.K. had full access to all data, and also reviewed all patient profiles for consistency (R.S. and E.D.K.). The decision to publish the data followed the independent data and safety monitoring committee recommendation for data release, and was supported by all coauthors.

The roles of employees of Novocure are described in the respective author contributions. Other employees' involvement was limited to technical support of the device.

**Additional Contributions:** We thank the patients and their families for participating in the trial. We are grateful to all of the EF-14 investigators, who are listed in eAppendix 4 in Supplement 2, and the nursing staff for taking care of the patients.

## Indications For Use and Safety Information in the United States:

Please visit [www.optune.com/IFU](http://www.optune.com/IFU) for Optune Instructions For Use (IFU) for complete information regarding the device's indications, contraindications, warnings and precautions.

Optune is intended as a treatment for adult patients (22 years of age or older) with histologically-confirmed glioblastoma multiforme (GBM).

Optune with temozolomide is indicated for the treatment of adult patients with newly diagnosed, supratentorial glioblastoma following maximal debulking surgery, and completion of radiation therapy together with concomitant standard of care chemotherapy.

For the treatment of recurrent GBM, Optune is indicated following histologically- or radiologically-confirmed recurrence in the supratentorial region of the brain after receiving chemotherapy. The device is intended to be used as a monotherapy, and is intended as an alternative to standard medical therapy for GBM after surgical and radiation options have been exhausted.

### Summary of Important Safety Information

#### Contraindications

Do not use Optune in patients with an active implanted medical device, a skull defect (such as, missing bone with no replacement), or bullet fragments. Use of Optune together with implanted electronic devices has not been tested and may theoretically lead to malfunctioning of the implanted device. Use of Optune together with skull defects or bullet fragments has not been tested and may possibly lead to tissue damage or render Optune ineffective.

Do not use Optune in patients that are known to be sensitive to conductive hydrogels. In this case, skin contact with the gel used with Optune may commonly cause increased redness and itching, and rarely may even lead to severe allergic reactions such as shock and respiratory failure.

#### Warnings and Precautions

Optune can only be prescribed by a healthcare provider that has completed the required certification training provided by Novocure (the device manufacturer).

Do not prescribe Optune for patients that are pregnant, you think might be pregnant or are trying to get pregnant, as the safety and effectiveness of Optune in these populations have not been established.

The most common ( $\geq 10\%$ ) adverse events involving Optune in combination with temozolomide were thrombocytopenia, nausea, constipation, vomiting, fatigue, medical device site reaction, headache, convulsions, and depression.

Use of Optune in patients with an inactive implanted medical device in the brain has not been studied for safety and effectiveness, and use of Optune in these patients could lead to tissue damage or lower the chance of Optune being effective.

If the patient has an underlying serious skin condition on the scalp, evaluate whether this may prevent or temporarily interfere with Optune treatment.

## Indications for use and safety information in Europe:

### Newly diagnosed GBM

Optune is intended for the treatment of patients with newly diagnosed GBM, after surgery and radiotherapy with adjuvant temozolomide, concomitant to maintenance temozolomide. The treatment is intended for adult patients, 18 years of age or older, and should be started more than 4 weeks after surgery and radiation therapy with adjuvant temozolomide. Treatment may be given together with maintenance temozolomide (according to the prescribing information in the Temodar package insert) and after maintenance temozolomide is stopped.

### Recurrent GBM

Optune is intended for the treatment of patients with recurrent GBM who have progressed after surgery, radiotherapy and temozolomide treatment for their primary disease. The treatment is intended for adult patients, 18 years of age or older, and should be started more than 4 weeks after the latest surgery, radiation therapy or chemotherapy.

#### Contraindications

Do not use Optune if you are pregnant, think you might be pregnant, or are trying to get pregnant. If you are a woman who is able to get pregnant, you must use birth control when using the device. Optune was not tested in pregnant women. Do not use Optune if you have clinically significant hepatic, renal or hematologic disease. Do not use Optune if you have significant additional neurological disease (primary seizure disorder, dementia, progressive degenerative neurological disorder, meningitis or encephalitis, hydrocephalus associated with increased intracranial pressure). Do not use Optune if you are known to be sensitive to conductive hydrogels like the gel used on electrocardiogram (ECG) stickers or transcutaneous electrical nerve stimulation (TENS) electrodes. In this case, skin contact with the gel used with Optune Treatment Kit may commonly cause increased redness and itching, and rarely may even lead to severe allergic reactions such as shock and respiratory failure.

#### Warnings and Precautions

Use Optune only after receiving training from qualified personnel, such as your doctor, a nurse, or other medical personnel who have completed a training course given by the device manufacturer (Novocure). All servicing procedures must be performed by qualified and trained personnel.

Do not use Optune Treatment Kit if you are 17 years old or younger. The system has not been tested in persons 17 years old or younger. It is unknown what side effects the device may cause in these cases or if it will be effective.

Do not wet the device or the transducer arrays. Do not use any parts that do not come with the Optune treatment kit, or that were not sent to you by the device manufacturer or given to you by your doctor.

Optune commonly causes skin irritation beneath the transducer arrays and in rare cases lead to headaches, falls, fatigue, muscle twitching or skin ulcers.

For complete information regarding Optune's indication, contraindication, warnings and precautions please see the [Instructions for Use \(IFU\)](http://www.optune.com/deutsch/materialien/schulungen.aspx). (<http://www.optune.com/deutsch/materialien/schulungen.aspx>)

# Effect of Tumor-Treating Fields Plus Maintenance Temozolomide vs Maintenance Temozolomide Alone on Survival in Patients With Glioblastoma

## A Randomized Clinical Trial

Roger Stupp, MD; Sophie Taillibert, MD; Andrew Kanner, MD; William Read, MD; David M. Steinberg, PhD; Benoit Lhermitte, MD; Steven Toms, MD; Ahmed Idubai, MD; Manmeet S. Ahluwalia, MD; Karen Fink, MD, PhD; Francesco Di Meco, MD; Frank Lieberman, MD; Jay-Jiguang Zhu, MD, PhD; Giuseppe Stragliotto, MD, PhD; David D. Tran, MD, PhD; Steven Brem, MD; Andreas F. Hottinger, MD, PhD; Eilon D. Kirson, MD, PhD; Gitit Lavy-Shahaf, PhD; Uri Weinberg, MD, PhD; Chae-Yong Kim, MD, PhD; Sun-Ha Paek, MD, PhD; Garth Nicholas, MD; Jordi Burna, MD; Hal Hirte, MD; Michael Weller, MD; Yoram Palti, MD, PhD; Monika E. Hegi, PhD; Zvi Ram, MD

**IMPORTANCE** Tumor-treating fields (TTFields) is an antimitotic treatment modality that interferes with glioblastoma cell division and organelle assembly by delivering low-intensity alternating electric fields to the tumor.

**OBJECTIVE** To investigate whether TTFields improves progression-free and overall survival of patients with glioblastoma, a fatal disease that commonly recurs at the initial tumor site or in the central nervous system.

**DESIGN, SETTING, AND PARTICIPANTS** In this randomized, open-label trial, 695 patients with glioblastoma whose tumor was resected or biopsied and had completed concomitant radiochemotherapy (median time from diagnosis to randomization, 3.8 months) were enrolled at 83 centers (July 2009-2014) and followed up through December 2016. A preliminary report from this trial was published in 2015; this report describes the final analysis.

**INTERVENTIONS** Patients were randomized 2:1 to TTFields plus maintenance temozolomide chemotherapy (n = 466) or temozolomide alone (n = 229). The TTFields, consisting of low-intensity, 200 kHz frequency, alternating electric fields, was delivered ( $\geq 18$  hours/d) via 4 transducer arrays on the shaved scalp and connected to a portable device. Temozolomide was administered to both groups (150-200 mg/m<sup>2</sup>) for 5 days per 28-day cycle (6-12 cycles).

**MAIN OUTCOMES AND MEASURES** Progression-free survival (tested at  $\alpha = .046$ ). The secondary end point was overall survival (tested hierarchically at  $\alpha = .048$ ). Analyses were performed for the intent-to-treat population. Adverse events were compared by group.

**RESULTS** Of the 695 randomized patients (median age, 56 years; IQR, 48-63; 473 men [68%]), 637 (92%) completed the trial. Median progression-free survival from randomization was 6.7 months in the TTFields-temozolomide group and 4.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.52-0.76;  $P < .001$ ). Median overall survival was 20.9 months in the TTFields-temozolomide group vs 16.0 months in the temozolomide-alone group (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ). Systemic adverse event frequency was 48% in the TTFields-temozolomide group and 44% in the temozolomide-alone group. Mild to moderate skin toxicity underneath the transducer arrays occurred in 52% of patients who received TTFields-temozolomide vs no patients who received temozolomide alone.

**CONCLUSIONS AND RELEVANCE** In the final analysis of this randomized clinical trial of patients with glioblastoma who had received standard radiochemotherapy, the addition of TTFields to maintenance temozolomide chemotherapy vs maintenance temozolomide alone, resulted in statistically significant improvement in progression-free survival and overall survival. These results are consistent with the previous interim analysis.

**Author Affiliations:** Author affiliations are listed at the end of this article.

**Corresponding Author:** Roger Stupp, MD, Lou and Jean Malnati Brain Tumor Institute of the Robert H. Lurie Comprehensive Cancer Center of Northwestern University, 676 N St Clair St, Ste 2210, Chicago, IL 60611 ([roger.stupp@northwestern.edu](mailto:roger.stupp@northwestern.edu)).

**G**lioblastoma is the most common and aggressive primary brain tumor with an annual incidence of 3.19 per 100 000.<sup>1-5</sup> The disease course is typically rapid, with only approximately 1 in 4 patients alive 2 years after diagnosis, and only 5% to 10% of patients alive at 5 years.<sup>1,6,7</sup>

Since the current standard of care was established, consisting of surgical resection or biopsy, followed by radiotherapy with concomitant temozolomide chemotherapy, followed by maintenance temozolomide for 6 to 12 months,<sup>6</sup> little progress has been made in the treatment of this disease.<sup>3,8,9</sup> Most trials have shown median progression-free survival and median overall survival from diagnosis of 6.2 to 7.5 months and 14.6 to 16.7 months, respectively.<sup>4-6,8</sup>

Tumor-treating fields (TTFields) are an antimetabolic treatment that selectively affects dividing glioblastoma cells by delivering low-intensity, intermediate-frequency (200 kHz) alternating electric fields via transducer arrays applied to the scalp.<sup>10,11</sup> Tumor-treating fields cause mitotic arrest and apoptosis of rapidly dividing cells.<sup>10,11</sup> Preclinical studies demonstrated increased sensitivity to chemotherapy with the addition of TTFields in human glioblastoma cell lines and in animal tumor models.<sup>12</sup> In a randomized phase 3 trial involving 237 patients with recurrent glioblastoma whose several lines of prior therapy had failed, TTFields monotherapy was compared with the treating physicians' best choice of salvage chemotherapy. Although no survival difference was observed, the higher objective response rate (12% vs 7%) suggested single-modality activity of TTFields.<sup>13</sup>

In 2009, this randomized phase 3 clinical trial was initiated, comparing maintenance temozolomide alone with maintenance temozolomide in combination with TTFields among patients with glioblastoma. A preplanned interim analysis involving the first 315 patients randomized was previously reported and demonstrated improved progression-free and overall survival.<sup>14</sup> This article reports the final analysis involving all 695 randomized patients, with a median follow-up of 40 months and a minimum follow-up of 24 months.

## Methods

The study was approved by the institutional review boards or ethics committees of all participating centers, and all patients provided written informed consent before entering the study. The trial protocol and statistical analysis plan are included in [Supplement 1](#).

## Study Population

Patients eligible for this study were aged 18 years or older, had a Karnofsky performance score of 70 or higher (a score of  $\geq 70$  ensures independence in activities of daily living), and had newly diagnosed and histologically confirmed supratentorial glioblastoma (World Health Organization [WHO] grade IV astrocytoma<sup>15</sup>). All participants had undergone maximal safe debulking surgery when feasible or biopsy and had completed standard radiotherapy with concomitant temozolomide at the time of enrollment. Prior use of implanted

## Key Points

**Question** Does the use of tumor-treating fields (TTFields), consisting of low-intensity, alternating electric fields delivered via transducer arrays applied to the scalp, when added to maintenance temozolomide chemotherapy, improve progression-free survival for patients with glioblastoma?

**Findings** In this randomized clinical trial involving 695 patients with glioblastoma who had completed initial radiochemotherapy, median progression-free survival from randomization was 6.7 months in the TTFields plus temozolomide group and 4.0 months in the temozolomide-alone group (hazard ratio, 0.63), a significant difference.

**Meaning** Among patients with glioblastoma, the addition of TTFields to maintenance temozolomide chemotherapy resulted in statistically significant improvement in survival. These results are consistent with those reported in a previous interim analysis.

carmustine wafers was allowed. Patients with evidence of progressive disease following radiochemotherapy, infratentorial tumor location, and severe comorbidities were excluded. Adequate hematological, liver, and kidney function tests to allow for temozolomide chemotherapy were required.<sup>6,14,16</sup>

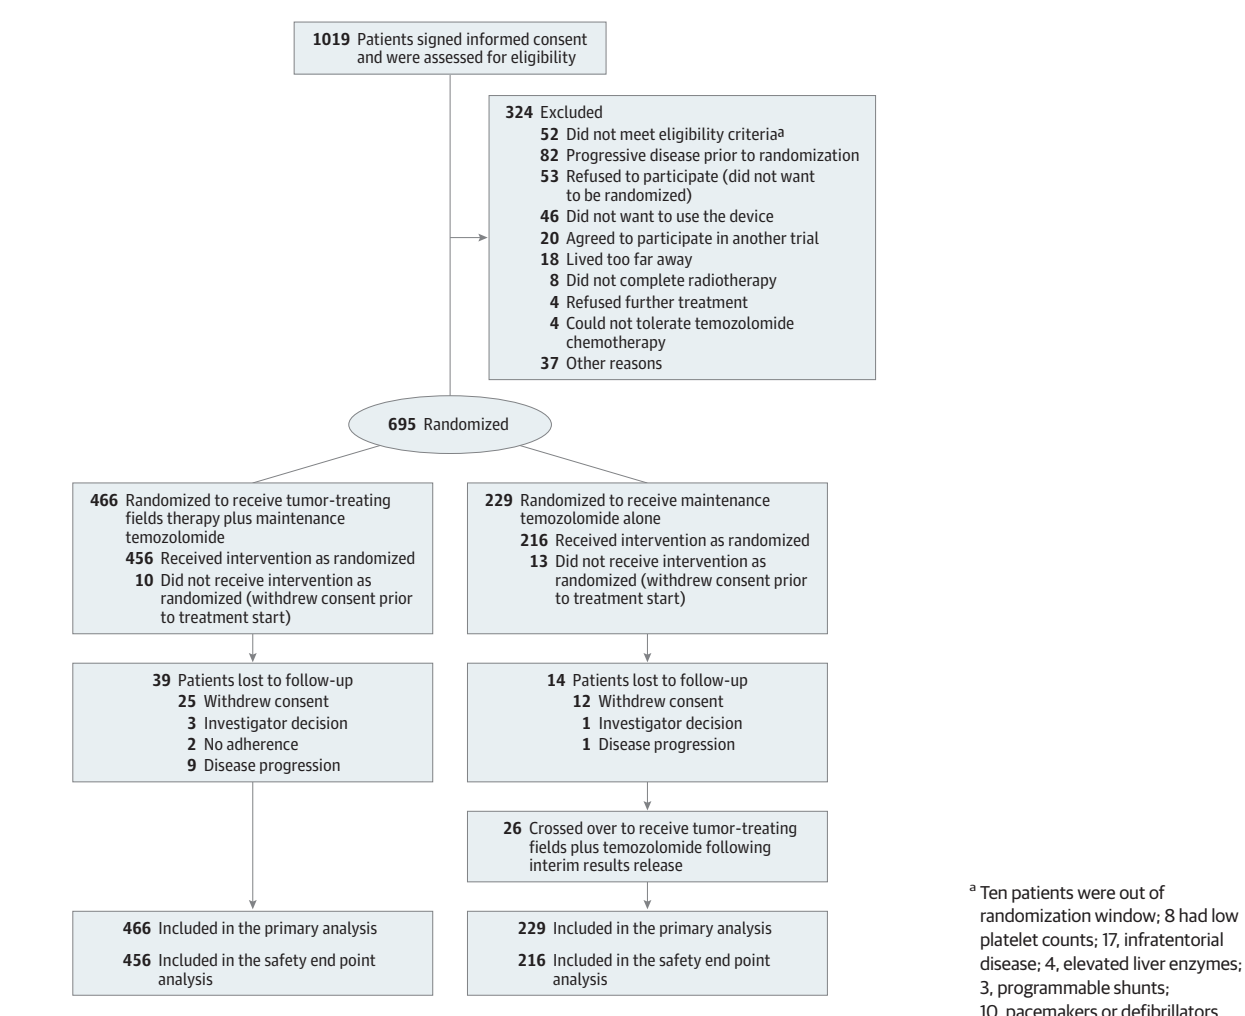

## Study Design and Treatment

This multicenter, open-label, randomized clinical phase 3 trial, recruited 695 patients at 83 sites in North America, Europe, the Republic of Korea, and Israel. The trial was designed to test the efficacy and safety of TTFields in combination with best standard of care in the treatment of newly diagnosed glioblastoma. Patients were randomized after the end of radiochemotherapy at a ratio of 2:1 to receive standard maintenance temozolomide chemotherapy (150-200 mg/m<sup>2</sup>/d for 5 days every 28 days for 6 cycles) with or without the addition of TTFields. Tumor treating fields treatment was to be initiated at least 4 weeks but not more than 7 weeks from the last day of radiotherapy. Maintenance temozolomide was delivered in 28-day cycles according to the protocol established by the European Organisation for Research and Treatment of Cancer (EORTC) Brain Tumor and Radiotherapy Groups and the National Cancer Institute of Canada (NCIC) Clinical Trials Group.<sup>6</sup> Extension of the duration of maintenance temozolomide beyond 6 cycles was allowed per local practice. Randomization was performed using a central web-based randomization system and was stratified by extent of resection (biopsy, partial resection, gross total resection) and by the methylation status of the O6-methylguanine-DNA methyltransferase (*MGMT*) gene promoter (methylated, unmethylated, unknown).

Treatment with TTFields was delivered through 4 transducer arrays with 9 insulated electrodes each placed on the shaved scalp and connected to a portable device set to generate 200-kHz electric fields within the brain (Optune, Novocure Inc). Transducer array layouts were determined using a TTFields mapping software system to optimize field intensity within the treated tumor (NovoTAL, Novocure Inc). Patients were trained by the nursing staff and device technician to operate the device independently, replace transducer arrays, and troubleshoot any

Figure 1. Recruitment and Inclusion of Patients in the Study

alarm conditions (eg, disconnected cables). All treatment was delivered on an outpatient basis and at home. The transducer arrays were supplied in individual sterile packages, and replaced by the patient, a caregiver, or a device technician twice a week. Although uninterrupted treatment was recommended, the patient could take short treatment breaks to tend to personal needs. The patient was advised to continue treatment for no fewer than 18 hours a day.

If tumor progression occurred, second-line therapy was offered per local practice. However, in the experimental group, TTFields could be continued until second radiologic progression occurred or for a maximum of 24 months.

### Patient Surveillance and Follow-up

Patients diagnosed with glioblastoma who had undergone surgical resection or biopsy and had received standard radiochemotherapy were randomized to receive either TTFields plus temozolomide or temozolomide alone between July 2009 and December 2014 (Figure 1). The database was locked for final analysis on December 28, 2016. Baseline contrast-enhanced magnetic resonance imaging (MRI) of the brain was required within 2 weeks before starting treatment with maintenance

temozolomide with or without TTFields. A complete physical examination and laboratory parameters were performed within 1 week of treatment start. Evaluation also included the EORTC QLQ-C30 quality-of-life questionnaire with its brain-specific module (BN-20)<sup>17,18</sup> and a Mini-Mental State Examination (a test result of 27-30 points is considered normal function). Patients were seen monthly for medical follow-up and routine laboratory examinations. Quality of life was assessed every 3 months.

Adverse events were recorded for 2 months after treatment discontinuation according to National Cancer Institute Common Toxicity Criteria (NCI-CTC) v3.0. Adverse events were presented descriptively as number and percentage of patients with each adverse event term for all patients available at the time of the analysis.

### Independent Radiological Review

Magnetic resonance imaging was performed at 2-month intervals until second progression. In the event of clinical progression, MRI was to be performed within 1 week after the investigator had become aware of it. All MRIs were reviewed by 2 blinded central independent radiologists (BioClinica Inc) and were evaluated for tumor response and progression (Macdonald criteria<sup>19</sup>). For cases

in which the 2 reviewers were not in agreement, a third blinded radiologist adjudicated between them.

### Central MGMT Testing, Pathology Review, and Molecular Analyses

In patients with paraffin-embedded tumor tissue available, evaluation of the *MGMT* methylation status was performed using quantitative methylation-specific polymerase chain reaction<sup>3,20</sup> by a central laboratory licensed by MDxHealth. If the *MGMT* methylation status could not be determined centrally prior to randomization, local *MGMT* methylation status was used for stratification. All data analyses were based on the central blinded assessment.

Patients were included based on initial local histological diagnosis. A retrospective pathology review and evaluation of molecular testing was performed by a neuropathologist (B.L.) and molecular biologist (M.E.H.). Deletion of chromosomal arms 1p and 19q and amplification of the epidermal growth factor receptor (*EGFR*) were evaluated by fluorescent in situ hybridization (FISH), immunohistochemistry (IHC), or both; and the mutation status of the isocitrate dehydrogenase 1 (*IDH1*) gene was determined by immunohistochemistry for the most common mutant *IDH1-R132H* as described previously.<sup>21</sup> For cases in which insufficient tissue was available for *EGFR* FISH, the result of *EGFR* IHC was used as a surrogate (Hirsch score,  $\geq 200$  amplified;  $< 200$ , not amplified).<sup>22</sup>

## Outcomes

### Primary and Secondary End Points

The primary end point was progression-free survival, and the secondary end point was overall survival, with analyses conducted in the intent-to-treat population.

The protocol defined that overall survival would be analyzed in a per-protocol population including only patients who received their original allocated treatments. However, 26 patients (11%) in the temozolomide-alone control group crossed over and received TTFields after December 2014, following release of the results of the interim analysis of the trial. These 26 patients had more favorable baseline characteristics than the rest of the control patients (*MGMT* methylated, 48%; Karnofsky performance score, 80-100; time from end of radiotherapy to randomization, 31 days) and received more cycles of temozolomide (median, 10.5 cycles). To avoid possible bias, these patients were analyzed as randomized in the control group according to the intent-to-treat principle.

### Exploratory End Points

Other predefined exploratory end points were percentage of patients alive and progression free at 6 months, annualized survival rates, quality of life, Mini-Mental State Examination, and Karnofsky performance score. The quality-of-life data are not reported in this article.

## Statistical Analysis

### Primary and Secondary End Points

For the primary end point of progression-free survival, the calculated sample size was 700 patients aimed to detect a hazard ratio (HR) of 0.78 or less, with 80% power allowing for 10%

loss to follow-up and a 2-sided  $\alpha = .05$ . Overall survival was a powered secondary end point in the study (80% power; HR, 0.76; 2-sided  $\alpha = .05$ ). To avoid multiplicity, overall survival was to be tested statistically only if the primary end point of the study was met.

To allow for 2 analyses in the trial, the final type I error of 0.05 was split between the interim and final analyses based on a standard  $\alpha$  spending function (Lan and DeMets<sup>23,24</sup>). The primary end point at the final analysis would be achieved if progression-free survival was significantly longer in the TTFields plus temozolomide group using a stratified log-rank test (stratified by the randomization strata) with an  $\alpha$  of .046 (an  $\alpha$  of 0.014 was spent on the interim analysis).

The secondary end point would be achieved at the final analysis if overall survival was significantly longer in the TTFields plus temozolomide group using a stratified log-rank test with an  $\alpha$  of .048 (an  $\alpha$  of .006 was spent on the interim analysis).

### Missing Data

For the analysis of progression-free survival patients were censored for progression when treatment was changed before evidence of progression (at the date of treatment change), at the date of their last MRI if lost to follow up, or upon reaching the cutoff date without progression. For the analysis of overall survival, patients without a known date of death were censored at the last known date they were documented to be alive.

### Exploratory End Points

The exploratory end points of annual survival rates and the rate of progression-free survival at 6 months were compared between groups using a 1-sided *Z* distribution of the Kaplan-Meier estimates of the survival rates at the defined time point. In addition, the Cox proportional hazards model was used to analyze both progression-free survival and overall survival controlling for treatment group, age, sex, *MGMT* methylation status (as determined by the central laboratory), tumor location in the brain, and country of residence (United States vs all other countries). The threshold for significant interactions in the model was specified at an  $\alpha$  of .05.

### Post Hoc Analysis

Post hoc analyses of prespecified subgroups (*MGMT* promoter methylation status, extent of resection (complete, partial resection, or biopsy), age (continuous), performance status (90-100 vs  $\leq 80$ ), sex, and geographic region (United States vs the rest of the world) was performed using a multivariate analysis testing the difference between treatment groups while controlling for the other prognostic factors.

### Analysis of Adverse Events and Tolerability

Differences in the incidence of adverse events between groups was tested using a  $\chi^2$  test at an  $\alpha$  of .05. The incidence of adverse events was also compared between groups after normalizing the incidence to the average treatment duration per group. Differences in the time to decline in Karnofsky performance score and Mini-Mental State Examination were tested using a log-rank test at an  $\alpha$  of .05. All analyses were performed using SAS version 9.4.

## Results

### Study Participants

Four hundred and sixty-six patients were randomized to receive TTFields plus temozolomide and 229 to receive temozolomide alone (Figure 1). Patient baseline characteristics were balanced between the 2 groups (Table 1). The median age was 56 years (interquartile range [IQR], 48-63 years), 68% were men, and median Karnofsky performance score was 90%. Eighty-nine percent of patients were white, and 49% of the patients were treated in the United States.

Fifty-four percent had undergone a gross total resection (>95% of the tumor removed; as assessed and reported by the surgeon), 13% of patients had a diagnostic biopsy only. Histological slides for central pathology review were available for

Figure 2. Kaplan-Meier Survival Curves for Patients Included in the Final Analysis in the Intent-to-Treat Population

A, Median progression-free survival from randomization for the tumor-treating fields (TTFields) plus temozolomide group was 6.7 months and was 4.0 months for the temozolomide-alone group (hazard ratio [HR], 0.63; 95% CI, 0.52-0.76;  $P < .001$ ). B, Median survival from randomization was 20.9 months for the TTFields plus temozolomide group vs 16.0 months for the temozolomide-alone group (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ). Median follow-up was 44 months (range, 25-91 months) in both groups.

434 of 695 patients (62%). The local diagnosis of glioblastoma was confirmed in 419 of 434 patients (97%). For 6 cases WHO grade II or III diagnoses were made, and for the remaining 9 patients, the available tissue for review did not allow for a definitive diagnosis or showed no tumor, yet all these patients were included in the intent-to-treat analysis. Tumor tissue for *MGMT* testing was available for 82% of the patients; of the cases with a valid test (518 of 571) 41% were *MGMT* methylated (40% TTFields plus temozolomide group and 45% for the temozolomide-only group). In 7% of tumors, expression of the *IDH1*-R132H mutant was demonstrated by a positive immunohistochemistry, *EGFR* was amplified in 40%.

Tumor location (lobe, hemisphere) in the brain was also comparable between the groups. The median time from histological diagnosis to randomization was 3.8 months (range, 1.7-6.2 months) for patients in the TTFields plus temozolomide group, and 3.7 months (range, 1.4-6.3 months) for those in the temozolomide-only group. Median time from the end of radiotherapy to randomization was 37 days in the TTFields plus temozolomide group and 36 days in the temozolomide-only group and occurred in most patients after starting of the first cycle of maintenance temozolomide. Median time from randomization to TTFields was 5 days (IQR, 3-7 days).

### Treatment Delivery

All patients had completed radiotherapy and concomitant temozolomide as per local practice. The median number of temozolomide cycles until first tumor progression was 6 (range, 0-51) for the TTFields plus temozolomide group and 5 (range, 0-33) for the temozolomide-only group; the median duration of TTFields treatment was 8.2 months (range, 0-82 months), 51% ( $n = 237$ ) of patients continued TTFields after the first progression.

### Efficacy End points

After a median follow-up of 40 months (IQR, 34-66 months), and a minimum follow-up of 24 months, the primary end point

of median progression-free survival was 6.7 months (95% CI, 6.1-8.1 months) for patients treated with TTFields plus temozolomide vs 4.0 months (95% CI, 3.8-4.4 months) for patients treated with temozolomide alone, for a proportional hazard ratio (HR) of 0.63 (95% CI, 0.52-0.76;  $P < .001$ ; stratified log-rank test; Figure 2A). For the secondary end point of overall survival, the median survival duration from randomization was 20.9 months (95% CI, 19.3-22.7 months) in the TTFields plus temozolomide group vs 16.0 months (95% CI, 14.0-18.4 months) in the temozolomide-only group, proportional HR of 0.63 (95% CI, 0.53-0.76;  $P < .001$ ; stratified log-rank test; Figure 2B).

In exploratory analyses, the percentage of patients alive at 2 years from randomization was 43% (95% CI, 39%-48%); at 3 years, 26% (95% CI, 22%-31%), and at 5 years, 13% (95% CI, 9%-18%) in the TTFields plus temozolomide group and for the temozolomide-only group at 2 years was 31% (95% CI, 25%-38%;  $P < .001$ ); at 3 years, 16% (95% CI, 12%-23%;  $P = .009$ ); and at 5 years, 5% (95% CI, 2%-11%;  $P = .004$ ). Progression-free survival at 6 months was 56% (95% CI, 51%-61%) for patients treated with TTFields plus temozolomide and 37% (95% CI, 30%-44%) with temozolomide only ( $P < .001$ ) (Table 2).

An exploratory Cox proportional hazards model adjusting for Karnofsky performance score, *MGMT* promoter methylation status, geographic region, age, tumor location, and extent of resection were consistent with the findings of the progression-free and overall survival analyses. The following factors were associated with longer overall survival: TTFields plus temozolomide treatment (HR, 0.63; 95% CI, 0.53-0.76;  $P < .001$ ), female sex (HR, 0.76, 95% CI, 0.63-0.92;  $P = .005$ ), methylated *MGMT* promoter (HR, 0.50; 95% CI, 0.41-0.62;  $P < .001$ ), younger age (as a continuous variable; HR, 0.978 per year; 95% CI, 0.969-0.985;  $P < .001$ ) and higher Karnofsky performance score (as a categorical variable in 10 point increments;  $P < .001$ ). Patients with frontal tumors had non-significantly longer survival (HR = 0.82, CI 0.67-1.01,  $P = .061$ ). Country of treatment and extent of resection were not

<sup>a</sup>Survival rates are actuarial estimates according to the Kaplan-Meier method.

Figure 3. Overall Survival for Each Prognostic Patient Subgroup of Patients Treated With Tumor-Treating Fields Plus Temozolomide vs Temozolomide Alone

Data points represent Cox hazard ratios of overall survival in each subgroup of patients treated with tumor-treating fields (TTFields) plus temozolomide compared with temozolomide alone and were adjusted for the other subgroups. Error bars represent 95% CIs of the hazard ratios. The Karnofsky performance score is measured from 0 to 100 in 10-point increments, with higher scores indicating better the patient performance status.

IQR, indicates interquartile range; MGMT, O<sup>6</sup>-methylguanine-DNA methyltransferase promoter region methylation status.

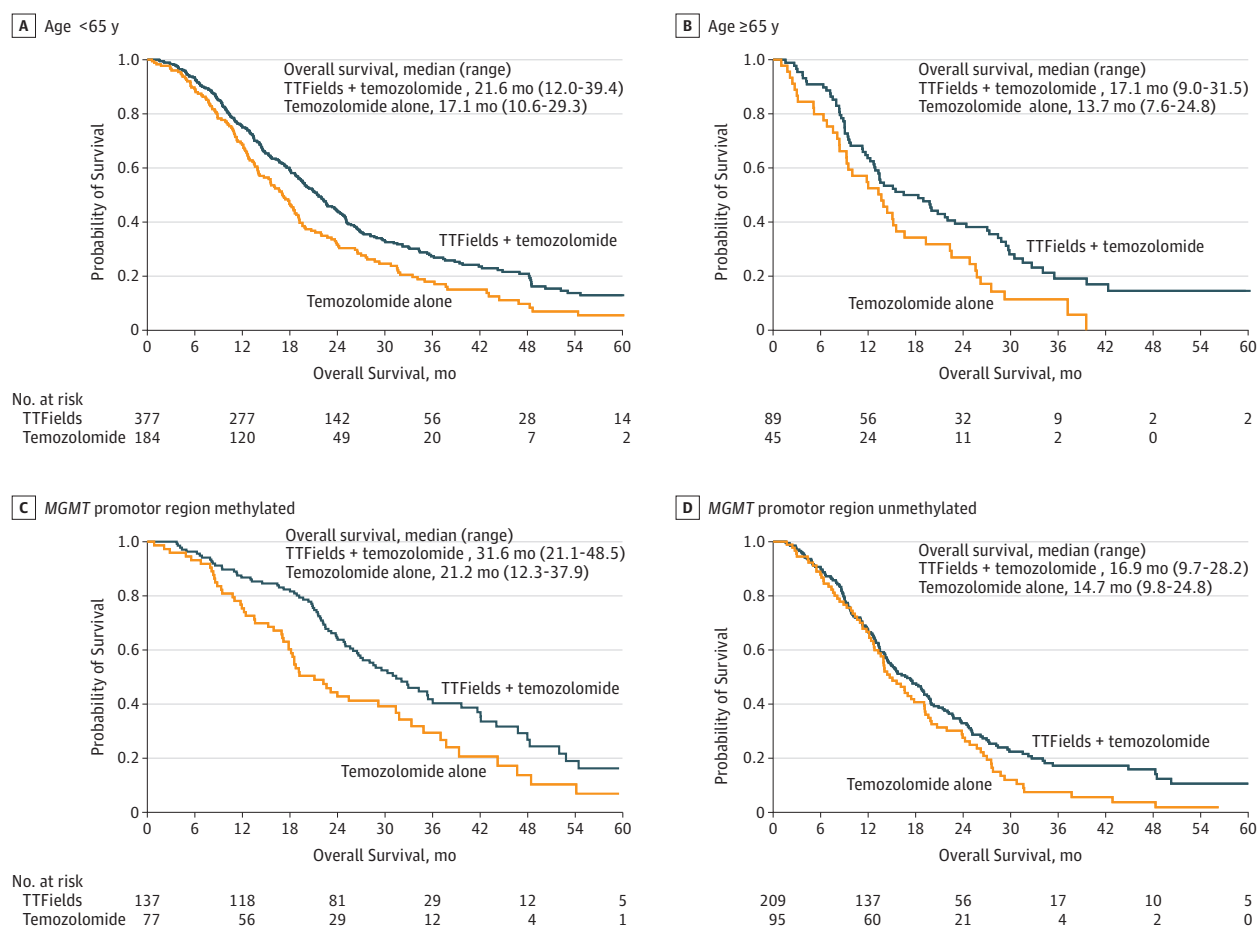

associated with a significant difference in survival ( $P = .101$  and  $P = .183$ , respectively).

### Post Hoc Subgroup Analysis

In post hoc analyses, TTFields plus temozolomide was associated with an increase in progression-free survival and overall survival (Figure 3; Cox proportional hazards,  $P < .05$  for the treatment effect within each subgroup) in all subgroups of

patients regardless of age, sex, Karnofsky performance score, MGMT promoter methylation status, geographic region, or extent of resection. Patients 65 years or older had shorter survival than patients younger than 65 years. In both age groups, TTFields plus temozolomide was associated with significantly increased survival compared with temozolomide alone for older (HR, 0.51; 95% CI, 0.33-0.77) and younger patients (HR, 0.67; 95% CI, 0.55-0.82; Figure 4A and Figure 4B).

Figure 4. Overall Survival by Patient Age and by *MGMT* Promotor Region Methylation Status

A, In comparing tumor-treating fields (TTFields) plus temozolomide vs temozolomide alone among patients younger than 65 years the hazard ratio (HR) was 0.67 (95% CI, 0.55-0.82). B, In comparing the 2 treatments among patients 65 years or older, the HR was 0.51 (95% CI, 0.22-0.77). C, In comparing the treatments among patients with O<sup>6</sup>-methylguanine-DNA methyltransferase

*MGMT* promotor region methylation, the HR was 0.62 (95% CI, 0.43-0.88). D, In comparing the treatments among patients without the *MGMT* promotor region methylation, the HR was 0.66 (95% CI, 0.49-0.85). The median follow-up of patients was 44 months (range, 25-91 months) in all groups.

Patients with tumors that lacked *MGMT* promoter methylation had a significantly shorter survival than patients with tumors with *MGMT* promoter methylation, although use of TTFields plus temozolomide was associated with longer survival (HR, 0.66; 95% CI, 0.49-0.85 both in patients with tumors that were *MGMT* methylated and tumors that were unmethylated, respectively; Figure 4C and Figure 4D). In the TTFields plus temozolomide group, 265 patients who were treated with TTFields for 18 hours a day or more (monthly average in the first 6 months of treatment) had longer survival than 185 patients treated less than 18 hours a day (22.6 months, 95% CI, 19.7-25.1 months vs 19.1 months, 95% CI, 16.5-21.9; HR, 0.65; 95% CI, 0.49-0.85;  $P = .009$ ).

### Adverse Events and Tolerability

The addition of TTFields to temozolomide therapy was not associated with any significant increase in rates of systemic adverse events compared with temozolomide therapy alone (48% vs 44%, respectively;  $P = .58$ ; Table 3), and the overall incidence,

distribution, and severity of adverse events were not statistically different in patients in the 2 treatment groups. The numerically higher incidence of some adverse events in the TTFields plus temozolomide group was a reflection of the longer duration of temozolomide treatment in this group due to delayed occurrence of progression. When adverse event incidence normalized to duration of treatment was analyzed, these differences disappeared. The only exception was a higher incidence of localized skin toxic effects (medical device site reaction beneath the transducer arrays) in patients treated with TTFields plus temozolomide; mild to moderate skin irritation was observed in 52% of patients, and severe (grade 3) skin involvement occurred in 2%. Anxiety, confusion, insomnia, and headaches which were reported more frequently (statistically nonsignificant) in patients treated with TTFields at the interim analysis were not seen in the final adverse event analysis of the trial. The incidence of seizures was identical in the 2 groups.

To estimate tolerability, prespecified exploratory analyses of the association of TTFields device use with patients'

<sup>a</sup> The numerically slightly higher incidence of hematological toxicity, fatigue, and some other adverse effects are due to the longer treatment duration and observation time in the experimental group. The differences disappear when data are normalized to treatment duration.

activities of daily life and cognition were performed using the Karnofsky performance score and the Mini-Mental State Examination. Time to a sustained 6-point decline in the Mini-Mental State Examination score was significantly longer in the TTFields plus temozolomide group than the temozolomide-alone group (16.7 months, 95% CI, 14.7-19.0 months vs 14.2 months, 95% CI, 12.7-17.0 months, respectively; HR, 0.79; 95% CI, 0.66-0.95;  $P = .01$ ). Time to a sustained 10-point decrease in Karnofsky performance score was also significantly longer in the TTFields plus temozolomide group than in the temozolomide-alone group (5.5 months, 95% CI, 5.0-6.3 months vs 3.9 months, 95% CI, 3.1-5.2 months, respectively; HR, 0.80; 95% CI, 0.67-0.95;  $P = .009$ ).

## Discussion

In the final analysis of this randomized phase 3 trial, the addition of the TTFields treatment to standard temozolomide maintenance therapy, compared with standard temozolomide maintenance therapy alone, resulted in increased progression-free survival and overall survival in patients with newly diagnosed glioblastoma. After a median follow-up of 40 months, the addition of TTFields to temozolomide, compared with temozolomide alone, resulted in longer median progression-free survival from the time of randomization, 6.7 months vs 4.0 months and longer median overall survival from randomization, 20.9 months vs 16.0 months, respectively. These findings are consistent with the preliminary results reported based on a planned interim analysis of the first 315 patients enrolled, after a median follow-up of 38 months, in which median progression-free survival in the intent-to-treat population was 7.1 months (95% CI, 5.9-8.2 months) in the TTFields plus temozolomide group (210 patients analyzed) and 4.0 months (95% CI, 3.3-5.2 months) in the temozolomide-alone group (105 patients analyzed).

In the current study, exploratory end points were consistent with the primary and secondary end points in this trial. In a post hoc analysis the effect of TTFields was observed in all clinical and molecular subgroups, including patients older than age 65 years and patients with *MGMT* unmethylated tumors.

To assess whether the improved outcome may have been related to other factors than the TTFields therapy the data were scrutinized for possible imbalances, unexpected poor performance of the control group, or differences in supportive care administered to patients between the 2 groups. Both clinical factors and molecular tumor characteristics were well balanced and comparable between the 2 groups. *MGMT* promoter methylation, the strongest predictive factor for outcome in temozolomide-treated patients,<sup>25</sup> was more prevalent in the control group (45% vs 40% of samples with a valid result). Patients with early tumor progression occurring during the first 3 months after diagnosis were not included in this trial, and so the randomized patient population had a better prognosis, for both groups, compared with other trials that had randomized patients before radiation therapy. The reported survival times were measured from randomization, not from diagnosis, so for an estimation of the overall outcome 3.8 months should be added in both groups. The RTOG 0525/Intergroup study, which evaluated dose-dense temozolomide, also randomized patients only after completion of radiochemotherapy.<sup>8</sup> Outcome of the control group in the current study and of the RTOG study were very similar, and in both studies, the median survival from randomization was 16 months.

In this trial, the rates of systemic adverse effects were not significantly different in the 2 treatment groups. The occurrence of mild to moderate skin irritation related to reaction beneath the transducer arrays of the device occurred in more than half of patients in the TTFields plus temozolomide group.

These findings are in contrast to the more than 23 randomized trials conducted over the last decade that have evaluated novel agents or intensified treatment strategies

(eg, dose-dense temozolomide, cilengitide, nimotuzumab, bevacizumab, and rindopepimut<sup>3,5,8,26</sup>) for treatment of patients with newly diagnosed glioblastoma and have failed to demonstrate improved survival. Innovative treatments for glioblastoma are needed.

### Limitations

This study has several limitations. First, the current trial was open-label because it was considered practically unfeasible (heat and easy measure of current associated with TTFields) and ethically unacceptable to expose patients to a sham device. Although a placebo effect may affect subjective end points like quality of life or even progression-free survival by influencing the frequency of imaging and its interpretation, in the current trial a consistent benefit was observed in progression-free survival as assessed by blinded central radiology review, as well as in the gold standard of objective outcome, overall survival. Second, delivery of TTFields therapy requires the patient to continuously carry a device on a

shaved scalp and may create burdens for patients. Nevertheless, the majority of patients were able to handle the device independently or with some help from a caregiver. The fact that 75% of patients achieved treatment adherence of 75% or more (ie, using the device for  $\geq 18$  hours per day) indicated good tolerability. The effects of the TTFields treatment and the need for continuous use of the device on quality of life will be reported separately.

### Conclusions

In the final analysis of this randomized clinical trial of patients with glioblastoma who had received standard radiochemotherapy, the addition of TTFields to maintenance temozolomide chemotherapy vs maintenance temozolomide alone, resulted in statistically significant improvement in progression-free survival and overall survival. These results are consistent with the previous interim analysis.

**Concept and design:** Stupp, Lieberman, Kiron, Palti, Ram.

### Acquisition, analysis, or interpretation of data:

Stupp, Taillibert, Kanner, Read, Steinberg, Lhermitte, Toms, Idhahbi, Alhuwalia, Fink, DiMeco, Lieberman, Zhu, Stragiolotto, Tran, Brem, Hottinger, Kiron, Lavy-Shahaf, Weinberg, Kim, Paek, Nicholas, Bruna, Hirte, Weller, Hegi, Ram.

**Drafting of the manuscript:** Stupp, Steinberg, Hottinger, Kiron, Lavy-Shahaf, Ram.

**Critical revision of the manuscript for important intellectual content:** Stupp, Taillibert, Kanner, Read, Lhermitte, Toms, Idhahbi, Alhuwalia, Fink, DiMeco, Lieberman, Zhu, Stragiolotto, Tran, Brem, Hottinger, Kiron, Weinberg, Kim, Paek, Nicholas, Bruna, Hirte, Weller, Palti, Hegi, Ram.

**Statistical analysis:** Steinberg, Kiron, Lavy-Shahaf.

**Obtained funding:** Kiron, Palti.

**Administrative, technical, or material support:** Stupp, Taillibert, Kanner, Read, Toms, DiMeco, Tran, Weinberg, Kim, Paek, Nicholas, Bruna, Weller, Palti.

**Supervision:** Stupp, Alhuwalia, DiMeco, Brem, Kiron, Paek, Bruna, Weller, Ram.

**Conflict of Interest Disclosures:** All authors have completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Dr Stupp reports fees paid to his institution for serving on advisory boards of Celgene, Novartis, AbbVie, and Merck KGaA (Darmstadt) and travel support from Novocure and that his spouse works full time for Celgene. Dr Taillibert reports that she receives fees for patients in clinical trials from the CRNO-private foundation of the neurology department in Salpêtrière Hospital. Dr Steinberg reports receiving serving as a statistical consultant for Novocure. Dr Toms reports receiving honoraria for serving on the strategic advisory board and lecturing for Novocure. Dr Idhahbi reports receiving research support from Foundation ARC, Beta-Innov, and Carthera; travel support from Hoffmann-La Roche and Carthera; serving on the editorial advisory board of *Lettre du Cancérologue*; serving on the advisory boards of Bristol-Myers Squibb and Hoffmann-La Roche; and receiving personal fees from Cipla. Dr Alhuwalia reports receiving grant support, personal fees, or both from Monther Medical, AbbVie, Bristol-Myers Squibb, AstraZeneca, Datar Genetics, CBT Pharmaceuticals, Kadmon Pharmaceuticals, Elsevier, Novocure,

Novartis, Incyte, Pharmacycics, Tracoon Pharmaceuticals, Prime Oncology, and Caris Lifesciences. Dr Fink reports serving in the speakers program for Genentech and receiving personal fees from Novocure and UCB Pharma. Dr Lieberman reports receiving grant support from Novocure, Stemline, and Roche. Dr Zhu reports receiving grant support from Novocure, Immuno-Cellular Therapeutics, Diffusion Pharmaceutical LLC, DEKK-TEC Inc, NRG Oncology/Radiation Therapy Oncology Group/National Cancer Institute, Boston Biomedical, Sumitomo Dainippon Pharma Global Oncology, Five Prime Therapeutics, Tocagen Inc, and Northwest Biotherapeutics. Dr Tran reports receiving grant support from Merck, Novartis, Northwest Biotherapeutics, Stemline, VBL Therapeutics, and Tocagen, receiving personal fees from Montheris, and serving on the advisory board of Novocure. Dr Hottinger reports receiving institutional grant support from Novocure and fees paid to his institution for serving on the advisory boards of Servier and Bristol-Myers Squibb. Dr Kiron reports that he is an employee of and owns stock in Novocure. Dr Lavy Shahaf reports that he is an employee of and owns stock in Novocure Ltd. Dr Weinberg reports that he is an employee of and owns stock in Novocure Ltd. Dr Weller reports receiving grant support or personal fees from Novocure, Acceleron, Actelion, Bayer, MSD, Merck EMD, Novocure, OGD2 Pharma, Piquor, Roche, Tragara, AbbVie, Bristol-Myers Squibb, Celldex, Pfizer, Progenics, Teva, Tocagen, and Orbus. Dr Palti reports serving as a consultant for, owning stock in, and having pending patents licensed through Novocure. Dr Hegi reports receiving financial support from Novocure, serving as an adviser to Bristol-Myers Squibb, and receiving nonfinancial support from MDxHealth. Dr Ram reports that he is a paid consultant for and owns stock in Novocure. No other disclosures were reported.

**Funding/Support:** The study was funded by Novocure Ltd.

**Role of the Funder/Sponsor:** Novocure Ltd had a role in the design and conduct of the study; collection, management, and analysis of the data; and decision to submit the manuscript for publication. The study was designed by Drs Stupp

and Ram, together with representatives from Novocure, mainly Dr Kirson. The study oversight was supported and monitored by a clinical research organization, which also held the database. Data were collected by the investigators and monitored by the clinical research organization. The data were analyzed by Dr Steinberg, the independent study statistician, and by Dr Lavy-Shahaf, the sponsor statistician. Data interpretation was the responsibility of Drs Stupp and Ram, with Dr Kirson, the study sponsor representative and project lead, all of whom jointly developed the first draft. A subsequent mature draft and prefinal version were circulated among all authors who gave additional input, contributed to, and approved the manuscript. Drs Stupp and Kirson reviewed all patient profiles for consistency. The decision to publish the data and its interpretation was made by Drs Stupp and Ram and was supported by all coauthors.

**Additional Contributions:** We thank the patients and their families for participating in the trial. We are grateful to all EF-14 investigators (whose names and institutions are listed in the eAppendix in Supplement 2) are grateful to the nurses who provided excellent care to the patients and the supporting staff for data management.

# Influence of Treatment With Tumor-Treating Fields on Health-Related Quality of Life of Patients With Newly Diagnosed Glioblastoma

## A Secondary Analysis of a Randomized Clinical Trial

Martin J. B. Taphoorn, MD; Linda Dirven, PhD; Andrew A. Kanner, MD; Gitit Lavy-Shahaf, PhD; Uri Weinberg, MD, PhD; Sophie Taillibert, MD; Steven A. Toms, MD; Jerome Honnorat, MD, PhD; Thomas C. **IMPORTANCE** Tumor-treating fields (TTFields) therapy improves both progression-free and overall survival in patients with glioblastoma. There is a need to assess the influence of TTFields on patients' health-related quality of life (HRQoL).

**OBJECTIVE** To examine the association of TTFields therapy with progression-free survival and HRQoL among patients with glioblastoma.

**DESIGN, SETTING, AND PARTICIPANTS** This secondary analysis of EF-14, a phase 3 randomized clinical trial, compares TTFields and temozolomide or temozolomide alone in 695 patients with glioblastoma after completion of radiochemotherapy. Patients with glioblastoma were randomized 2:1 to combined treatment with TTFields and temozolomide or temozolomide alone. The study was conducted from July 2009 until November 2014, and patients were followed up through December 2016.

**INTERVENTIONS** Temozolomide, 150 to 200 mg/m<sup>2</sup>/d, was given for 5 days during each 28-day cycle. TTFields were delivered continuously via 4 transducer arrays placed on the shaved scalp of patients and were connected to a portable medical device.

**MAIN OUTCOMES AND MEASURES** Primary study end point was progression-free survival; HRQoL was a predefined secondary end point, measured with questionnaires at baseline and every 3 months thereafter. Mean changes from baseline scores were evaluated, as well as scores over time. Deterioration-free survival and time to deterioration were assessed for each of 9 preselected scales and items.

**RESULTS** Of the 695 patients in the study, 639 (91.9%) completed the baseline HRQoL questionnaire. Of these patients, 437 (68.4%) were men; mean (SD) age, 54.8 (11.5) years. Health-related quality of life did not differ significantly between treatment arms except for itchy skin. Deterioration-free survival was significantly longer with TTFields for global health (4.8 vs 3.3 months;  $P < .01$ ); physical (5.1 vs 3.7 months;  $P < .01$ ) and emotional functioning (5.3 vs 3.9 months;  $P < .01$ ); pain (5.6 vs 3.6 months;  $P < .01$ ); and leg weakness (5.6 vs 3.9 months;  $P < .01$ ), likely related to improved progression-free survival. Time to deterioration, reflecting the influence of treatment, did not differ significantly except for itchy skin (TTFields worse; 8.2 vs 14.4 months;  $P < .001$ ) and pain (TTFields improved; 13.4 vs 12.1 months;  $P < .01$ ). Role, social, and physical functioning were not affected by TTFields.

**CONCLUSIONS AND RELEVANCE** The addition of TTFields to standard treatment with temozolomide for patients with glioblastoma results in improved survival without a negative influence on HRQoL except for more itchy skin, an expected consequence from the transducer arrays.

**TRIAL REGISTRATION** clinicaltrials.gov Identifier: NCT00916409

Glioblastoma has a poor prognosis,<sup>1,2</sup> and, as tumors grow, patients often experience a progressive decline in neurologic function and health-related quality of life (HRQoL).<sup>3-7</sup> The current standard of care is not curative but results in prolongation of life. However, extension of survival is meaningful only if patients' functioning and well-being can be retained or improved.<sup>8-11</sup> Therefore, it is important to determine the net clinical benefit of each new treatment or treatment modality introduced; possible benefits of a new treatment, in terms of prolonged survival, have to be carefully weighed against potential negative effects of the treatment on the patients' quality of life.

The current standard of care for patients with newly diagnosed glioblastoma comprises surgical resection to the extent safely feasible followed by radiotherapy with concomitant and maintenance chemotherapy with temozolomide.<sup>12</sup> Tumor-treating fields (TTFields) (Optune; Novocure Ltd) is an antimitotic physical treatment modality<sup>13,14</sup> delivered by a home use medical device with wired transducer arrays placed on the patients' scalp. When added to standard maintenance temozolomide chemotherapy, TTFields has been demonstrated to improve both progression-free survival and overall survival in a randomized clinical trial (NCT00916409).<sup>15</sup>

Treatment with TTFields involves the patient carrying a mobile electrical device for more than 18 hours per day and having 4 arrays of transducers continuously fixed to the shaved scalp. Concerns regarding the influence of wearing the device on patients' HRQoL have therefore been raised.<sup>16,17</sup> The incidence of adverse events was not increased by the addition of TTFields to temozolomide therapy except for an expected mild to moderate skin irritation beneath the electrodes in 52% of patients (severe in 2%). Herein, we report on the influence of treatment with TTFields on the patients' HRQoL, which was a predefined secondary objective of the randomized clinical trial. The present study was conducted from July 2009 until November 2014, and patients were followed up through December 2016.

## Methods

### Study Population

Patients eligible for this study were aged 18 years or older, had newly diagnosed and histologically confirmed supratentorial glioblastoma (World Health Organization grade IV astrocytoma), were progression free after undergoing maximal safe debulking surgery or biopsy, and had completed standard radiotherapy with concomitant temozolomide. Patients were required to have a Karnofsky Performance Status score of at least 70 at the time of enrollment, corresponding to at least being able to perform self-care. Further details on the study population are available elsewhere.<sup>15</sup> All patients provided written informed consent, and the study was approved by the institutional review boards or ethics committees of all participating centers and the relevant competent authorities (eAppendix 1 in Supplement 1); the participants did not receive financial compensation.

### Key Points

**Question** What is the influence of adding tumor-treating fields to the standard treatment on health-related quality of life in patients with glioblastoma?

**Findings** In this secondary analysis of the EF-14 randomized clinical trial, the addition of tumor-treating fields did not negatively influence health-related quality of life except for itchy skin, an expected consequence from the transducer arrays.

**Meaning** Tumor-treating field therapy has previously been shown to prolong both progression-free and overall survival. When considering the net clinical benefit, improved survival without a negative influence on health-related quality of life supports the addition of tumor-treating fields to standard treatment in patients with glioblastoma.

### Study Design and Treatment

This prospective, multicenter, open-label, randomized clinical phase 3 trial recruited 695 patients at 90 medical centers in North America, Europe, the Republic of Korea, and Israel. The trial protocol is available in Supplement 2. The trial was designed to test the efficacy of TTFields in combination with the best standard of care in the treatment of newly diagnosed glioblastoma (ie, radiotherapy with concomitant and adjuvant temozolomide). The primary end point was progression-free survival, with overall survival as a powered secondary end point. Health-related quality of life was a secondary end point. Patients who were progression free after completion of radiochemotherapy were randomized within 4 to 7 weeks at a ratio of 2:1 to receive standard maintenance temozolomide chemotherapy (150-200 mg/m<sup>2</sup> for 5 days every 28 days for 6 cycles) with or without the addition of TTFields. If tolerated well, TTField therapy was to be continued until the second progression or up to 2 years.

Patients in the TTFields plus temozolomide group received continuous TTFields combined with maintenance temozolomide. TTFields were delivered through a portable device in an outpatient setting. Patients receiving TTFields had 4 transducer arrays with 9 insulated electrodes each placed on the shaved scalp and connected to a portable device set to generate 200-kHz electric fields within the brain. Although uninterrupted treatment was recommended, the patient could take short breaks if needed; patients were advised to continue treatment for at least 18 hours a day. More details on the study design and treatment are published elsewhere.<sup>15</sup>

### HRQoL Assessment

The evaluation of HRQoL was performed using the validated European Organisation for Research and Treatment of Cancer (EORTC) quality-of-life questionnaire (QLQ-C30) and brain module (QLQ-BN20).<sup>18-20</sup> Questionnaires were completed on paper at baseline (prior to randomization) and subsequently every 3 months for up to 12 months. Nine scales and items were preselected as important based on relevance for patients with glioblastoma and hypothesized effects of the TTFields delivery device on patients' HRQoL: global health status; physical, cognitive, role, social, and emotional functioning; itchy skin;

pain; and weakness of legs. We hypothesized that any burden of carrying the device (on physical functioning and itchy skin) or detriment to social and role functioning due to the visibility of the therapy may be balanced by patients' feeling of well-being (global health status and emotional functioning) related to active participation of both the patient and the caregiver in the fight against cancer and increasing patient empowerment. Moreover, we hypothesized that treatment with TTFields would not have an influence on cognitive functioning, pain, and weakness of legs.

### Statistical Analysis

#### Calculation of HRQoL Scores

The items on both questionnaires were scaled and scored using the recommended EORTC procedures.<sup>21</sup> Raw scores were transformed to a linear scale ranging from 0 to 100, with a higher score representing a higher level of functioning or higher level of symptoms. The results of this study are presented in accordance with guidelines for reporting HRQoL in cancer clinical trials and methods.<sup>22-24</sup> Differences of at least 10 points (on a 0-100 scale) were classified as the minimum clinically meaningful change in any HRQoL scale/item.<sup>24</sup>

#### Descriptive Statistics

Descriptive statistics were used to report HRQoL scores as well as the sociodemographic and clinical variables for the population of patients who completed at least 1 HRQoL scale at baseline separately for both treatment groups. Means and SDs or medians and ranges were calculated for continuous variables depending on the distribution of the variable. Frequencies and percentages were calculated for nominal variables. Differences between arms were tested using a 2-sided  $\chi^2$  test or an independent 2-tailed, unpaired *t* test or Mann-Whitney test at an  $\alpha$  value of .05 for each variable.

Adherence to HRQoL assessments was calculated as the number of forms received divided by the number of forms expected at every assessment. Patients who completed the assessments at the time of progression were included in this analysis.

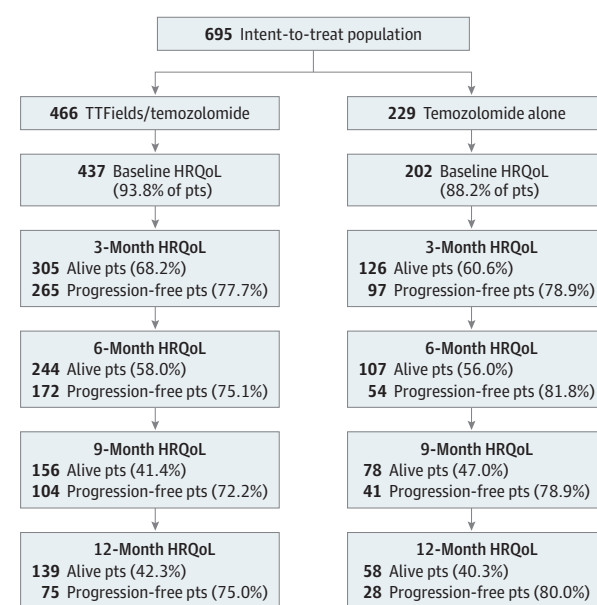

#### HRQoL Scores Over Time

Mean HRQoL scores over time were calculated as well as the mean changes from baseline. A stable HRQoL score was defined as a change of less than 10 points, and a change of 10 or more points indicated a deterioration or improvement depending on the scale or item. Mean change from baseline was plotted to evaluate the longitudinal course of patients' experience of disease and treatment, and a linear mixed-model repeated-measures analysis was used to estimate the treatment effect over time. A sensitivity analysis of complete cases using multiple imputations with a predictive mean matching regression model was used to check the robustness of the treatment effect over time. An additional sensitivity analysis used a repeated-measures model that assumes there is random variation among participants that is related to the time of dropout.

#### Stable or Improved HRQoL During the Progression-Free Period

The percentage of patients with stable (<10-point change) or improved ( $\geq$ 10-point change) HRQoL during the progression-

Figure 1. Consort Diagram

Data are the number and percentage of patients in the categories (baseline, alive, and progression-free) who completed the health-related quality-of-life (HRQoL) questionnaire at the indicated times. pts indicates patients; TTFields, tumor-treating fields.

free period, thus excluding the HRQoL assessment at progression, was determined separately for both treatment arms. This calculation was based on the total number of patients with a valid baseline HRQoL assessment and at least 1 additional follow-up assessment. Moreover, the area under the curve of stable or improved HRQoL for the entire duration of stability or improvement was determined, and differences between arms were assessed with the trapezoidal method (eAppendix 2 in Supplement 1).

#### Deterioration-Free Survival and Time to Deterioration

Deterioration-free survival was defined as the time to a greater than 10-point deterioration in scores from baseline without a subsequent 10-point or more improvement in scores compared with baseline, progressive disease, or death in the absence of a previous definitive deterioration before the next assessment. Disease progression was included as a surrogate measure. Data were censored at the last HRQoL assessment date for patients with a change of less than 10 points, patients who did not progress, or patients who died after 9 weeks since the last assessment. Data for patients with missing baseline scores were not included, and patients missing all postbaseline HRQoL assessments were censored at randomization. Time to deterioration (TTD) was defined similarly to deterioration-free survival, with the exception that progressive disease was excluded as an event (ie, nonmissing HRQoL data beyond progression were included). Kaplan-Meier methodology was used to estimate deterioration-free survival and TTD distributions and median times, and 95% CIs were computed using the Greenwood formula. The difference between treatment arms

was compared using a 2-sided stratified log-rank test. Hazard ratios were estimated using a stratified (for extent of resection and *MGMT* status) Cox proportional hazards regression model.

SAS, version 9.4 (SAS Institute) was used for all statistical analyses, and comparisons between groups were based on the intent-to-treat principle. *P* values <.05 were considered to be

Figure 2. Changes in Global Health Status and Itchy Skin

Mean changes in points on health-related quality of life scales from baseline in global health status (A) and itchy skin with (B) with tumor-treating fields (TTFields) plus temozolomide compared with temozolomide alone. No change,

between 0 and 10 points; improvement and deterioration, changes of 10 points or more. Error bars indicate SD.

statistically significant. The Hochberg procedure was used to adjust for the multiplicity of treatment comparisons in the pre-selected HRQoL scales analyses.

## Results

### Patients

A total of 695 patients were randomly assigned in a 2:1 ratio to TTFields plus temozolomide ( $n = 466$ ) or temozolomide alone ( $n = 229$ ). A total of 639 (91.9%) patients completed at least 1 HRQoL scale at baseline: 437 (93.8%) of those in the TTFields plus temozolomide arm and 202 (88.2%) patients in temozolomide-alone arm (Figure 1). The baseline demographics of the patients who provided HRQoL data were comparable to those of the intention-to-treat population<sup>15</sup> and were well balanced between treatment arms in this subpopulation (Table 1).

### HRQoL Completion Rates and Baseline Scores

Adherence to HRQoL assessments decreased from 91.9% at baseline to 65.8% (431 of 655 patients alive) at 3 months and dropped to 41.7% (197 of 473 patients alive) at 12 months of follow-up (Figure 1). Mean and median baseline HRQoL scores were comparable between arms for all preselected scales/items (eTable 1 in Supplement 1), as well as the exploratory scales and items. Reference values of HRQoL scores of a healthy general population<sup>25</sup> were available for 7 of 9 predefined scales and items (except itchy skin and weakness of legs). Patients with glioblastoma after completion of radiochemotherapy showed clinically relevant worse functioning or more symptoms compared with the general population on all scales except pain, which was similar.<sup>25</sup>

### Mean Changes in HRQoL From Baseline and the Repeated-Measures Mixed-Effect Model

Mean changes in HRQoL over time for the global health status is presented in Figure 2A and for all 9 predefined HRQoL scales

in the eFigure in Supplement 1. Throughout the 12-month assessment period, mean changes from baseline were stable (<10-point change from baseline) for all 9 predefined HRQoL scales in both treatment arms (eFigure in Supplement 1) with the exception of itchy skin (Figure 2B). For itchy skin, a clinically relevant deterioration (ie, an increase in itchy skin) compared with baseline was seen at the month 3 evaluation in the TTFields plus temozolomide arm (mean [SD] increase, 10.4 [30.1] points vs an improvement of 2.3 [24.4] points in the temozolomide arm). For differences between treatment arms, patients treated with TTFields plus temozolomide had significantly and clinically relevant worse itchy skin at 3, 6, and 9 months than patients treated with temozolomide alone, but not at 12 months (mean [SD] increase of 10.4 [30.1] in the TTFields plus temozolomide arm vs a decrease of 2.3 [24.4] in the temozolomide-alone arm,  $P = .005$ ; increase of 8.1 [31.6] in the TTFields plus temozolomide arm vs a decrease of 4.2 [31.4] in the temozolomide-alone arm,  $P = .008$ ; increase of 5.3 [28.0] in the TTFields plus temozolomide arm vs a decrease of 5.2 [29.6] in the temozolomide-alone arm,  $P = .04$ ; increase of 4.6 [32.8] in the TTFields plus temozolomide arm vs a decrease of 1.9 [36.9] in the temozolomide-alone arm,  $P = .66$ , respectively). For all other scales, there were no statistically significant or clinically relevant differences between treatment arms.

The repeated-measures mixed-effect model supported this finding, with no statistically significant difference between treatment arms in HRQoL scores over time in any predefined scale or item except for itchy skin ( $P < .001$ ), which was worse in the TTFields plus temozolomide arm (eTable 2 in Supplement 1). The sensitivity analyses showed that the results of the linear mixed model were robust.

### Stable or Improved HRQoL During Progression-Free Time

Compared with baseline, more patients in the TTFields plus temozolomide arm compared with the temozolomide-alone arm reported stable or improved scores for global health status (53.5% vs 38.0%, respectively,  $P = .001$ ), physical func-

Median CFB AUC until last stable/improved status (95% CI)	0 (0 to 0)	0 (−102.2 to 0)	.19	

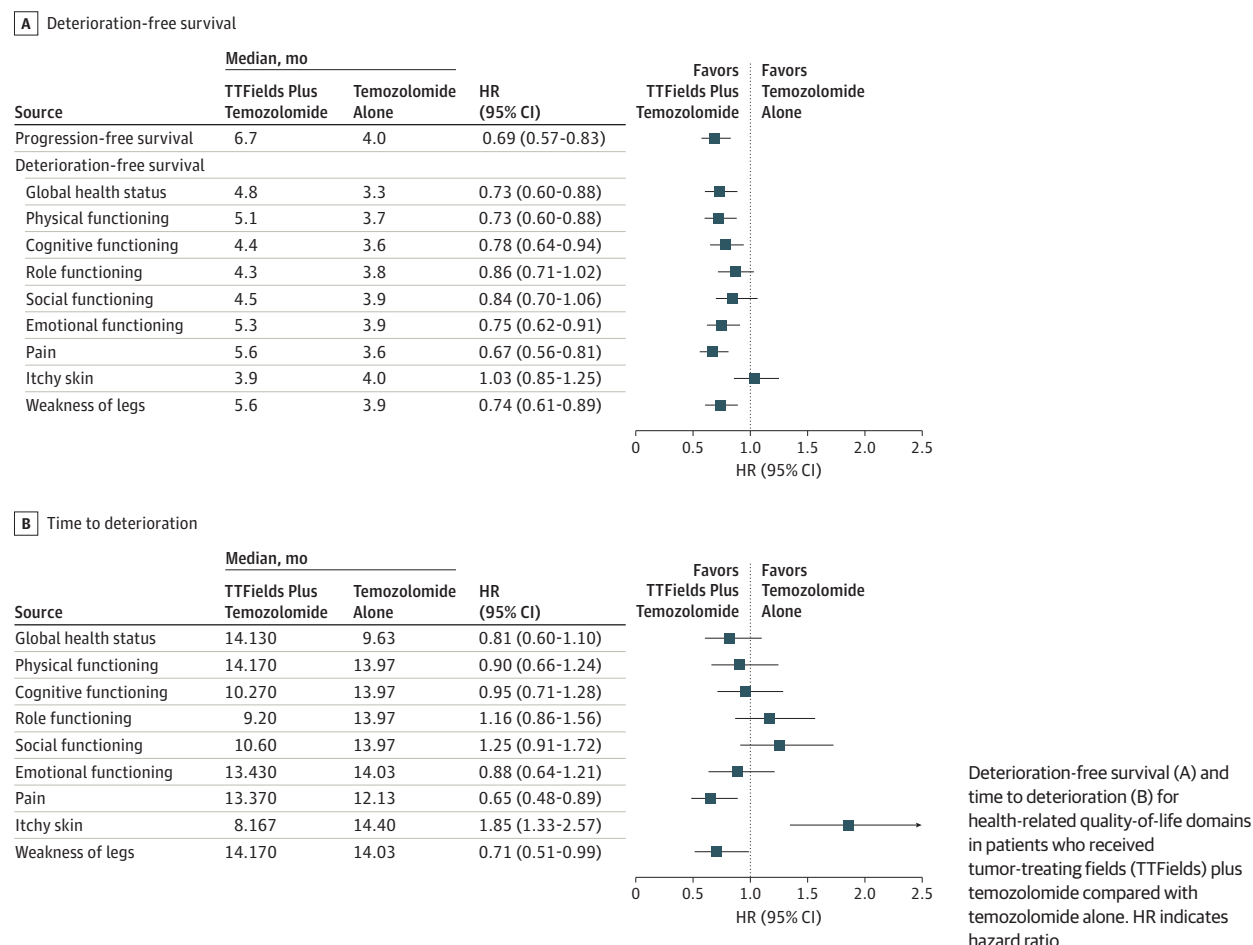

Abbreviations: AUC, area under the curve; CFB, change from baseline; TTFields, tumor-treating fields.

tioning (54.0% vs 37.0%, respectively;  $P = .001$ ), pain (56.8% vs 35.9%, respectively;  $P < .001$ ), and weakness of legs (58.7% vs 42.0%, respectively;  $P = .001$ ) but not in any of the other HRQoL scales and items. However, the duration of stable or improved HRQoL was shorter in the TTFields plus temozolomide arm, although not significantly different from the temo-

zolomide arm for any of the HRQoL scales and items. Overall, with a combination of these measures, the area under the curve analysis showed no significant differences between treatment arms for any of the HRQoL scales and items, indicating a similar HRQoL between treatment arms while patients did not experience tumor progression (Table 2).

Figure 3. Deterioration-Free Survival and Time to Deterioration

### Deterioration-Free Survival and TTD

The addition of TTFields to standard temozolomide chemotherapy resulted in statistically significant longer deterioration-free survival in global health status, physical and emotional functioning, pain, and weakness of legs (Figure 3A and eTable 2 in Supplement 1); the significant difference remained after correction for multiple testing. When progression was removed as a deterioration event (TTD), there was no negative influence of TTFields plus temozolomide treatment on the TTD of HRQoL (Figure 3B) except for itchy skin, which was worse in the TTFields plus temozolomide arm (8.2 vs 14.4 months). In contrast, the addition of TTFields to temozolomide resulted in a statistically significant prolongation until deterioration for pain (13.4 vs 12.1 months,  $P < .01$ ). There were no other significant differences in TTD between arms (Figure 3B).

### Discussion

In our detailed analysis of HRQoL during therapy with TTFields in addition to temozolomide, no significant difference was found between the groups in patients' HRQoL over time except for the skin reaction. As expected, itchy skin was reported more frequently in patients treated with TTFields be-

cause of the transducer arrays that have to be placed on the scalp of the patient. Consistently, over half of the patients also reported skin irritation as an adverse event. We had hypothesized that patients treated with TTFields may have better HRQoL in some domains as a result of active participation in the fight against cancer and the frequent interactions between patients and caregivers and device technicians regarding the device. However, on a group level, global health status and emotional functioning were not significantly different between treatment arms. Likewise, our hypotheses that the addition of TTFields would result in worse role and social functioning (due to the visibility of the device) and worse physical functioning were not confirmed. In line with our hypotheses, cognitive functioning, pain, and weakness of legs were not negatively affected by the addition of TTFields to temozolomide treatment. Most relevant for patients, HRQoL was maintained (in 8 of 9 of the predefined scales/items) over time. Combining the results of the survival and HRQoL analyses suggests that the addition of TTFields to adjuvant temozolomide is of value to patients with glioblastoma.

Patients who received TTFields had significantly longer deterioration-free survival compared with those in the temozolomide-alone arm for global health status (4.8 vs 3.3 months;  $P < .01$ ), physical (5.1 vs 3.7 months;  $P < .01$ ) and

emotional functioning (5.3 vs 3.9 months;  $P < .01$ ), pain (5.6 vs 3.6 months;  $P < .01$ ), and weakness of legs (5.6 vs 3.9 months;  $P < .01$ ). For the other scales and items, there was no significant difference in deterioration-free survival between the 2 treatment arms. The prolonged deterioration-free survival for these scales is explained by the extended progression-free survival for patients in the combined TTFields plus temozolomide arm, as progressive disease is included as an event in this analysis. Therefore, TTD analyses, excluding progressive disease as an event, is important to illustrate the influence of a treatment on HRQoL: TTD was not significantly different across any HRQoL scale or item in TTFields-treated patients except for pain and itchy skin, indicating that treatment with TTFields had an influence only on the level of pain and itchy skin. In patients treated with TTFields, TTD was significantly longer for pain (13.4 vs 12.1 months;  $P < .01$ ) and significantly shorter for itchy skin (8.2 vs 14.4 months;  $P < .001$ ). The difference between deterioration-free survival and TTD indicates the importance of disease progression (rather than treatment) as a key event driving HRQoL decline, as suggested by previous studies.<sup>26,27</sup> Moreover, in only 1% of patients, regardless of treatment arm, was a clinically relevant improvement in HRQoL seen after initial deterioration, supporting this observation. Taken together, the results of the deterioration-free survival and TTD analyses support the results of the longitudinal analysis by showing that the addition of TTFields to the standard of care did not adversely affect HRQoL. In fact, the delay in TTD for pain seen in TTFields-treated patients may reflect a delay in the occurrence of tumor-related headaches (although not significant, patients in the TTFields plus temozolomide arm had a longer TTD compared with patients in the temozolomide-alone arm for headaches: hazard ratio, 0.77; 95% CI, 0.54-1.10;  $P = .16$ ). Future studies are needed to better understand this finding, as the median TTD values for pain were longer than the median progression-free survival for both arms.

## Limitations

A common problem in many cancer clinical trials, as in this study, is missing HRQoL data. This absence is especially apparent during the follow-up period, hampering longitudinal data analysis. Patients with better prognostic factors and a good treatment response will be overrepresented at later stages.<sup>28,29</sup> However, our mixed-model analyses, accounting for missing data, confirmed the results found in the mean change from baseline analyses. Another limitation of clinical trials is generalizability of results—patients in clinical trials may not be representative of a general glioblastoma population. Patients in this trial were included only if they successfully completed the combined radiochemotherapy. In addition, it may be that not all patients are prepared to accept wearing the TTFields device. Nevertheless, patients participating in this trial were similar with respect to clinical characteristics to those participating in the EORTC 26981 study<sup>12</sup> comparing radiotherapy alone with radiotherapy plus temozolomide. Lastly, many factors may affect HRQoL, such as age, comorbidity, tumor characteristics, previous antitumor treatment (eg, radiation dose), and supportive treatment. However, it is unlikely that these factors influenced our conclusion, as the objective of this study was to compare HRQoL results between 2 treatment arms in which patients were similar due to randomization.

## Conclusions

Use of TTFields prolongs progression-free and overall survival in patients with glioblastoma. The addition of this novel device-delivered treatment neither negatively affects nor improves functioning and well-being of the patient, including critical HRQoL issues, such as role, social, and physical functioning. Patients reported more itchy skin, which is a direct and expected consequence of the placement of transducer arrays on the patients' scalp. Considering the net clinical benefit, our HRQoL data support the addition of TTFields to standard therapy in patients with glioblastoma.

Kanner, Lavy-Shahaf, Weinberg, Taillibert, Toms, Chen, David, Kim, Hottinger, Kew, Roth, Villano, Stupp.

**Study supervision:** Bruna, Roth, Desai, Villano, Kirson, Ram, Stupp.

**Conflict of Interest Disclosures:** Dr Taphoorn has performed paid consultancy for Hoffmann-La Roche. Dr Lavy-Shahaf is an employee of and received personal fees from Novocure during the conduct of the study. Drs Weinberg and Kirson are employees of and own minority stock in Novocure. Dr Taillibert received fees from Centre-de-Recherche-en-Neuro-Oncologie for enrolling patients at Salpêtrière University Hospital during the conduct of the study. Dr Idhahbi received research support from Foundation ARC, IntselChimos, Beta-Innov, and Carthera and travel support from Carthera and Hoffmann-La Roche and served as a paid member of the advisory boards of BMS, Hoffmann-La Roche, and Lettre du Cancérologue. Dr Hottinger received research support from Novocure and served on advisory boards of Servier and BMS (fees paid to the institution). Dr Roth served as a paid member of the advisory boards of Roche and MSD and received personal fees for lectures on behalf of BMS and Novocure. Dr Ram received grants and personal fees from and owns minority stock in Novocure. Dr Stupp received nonfinancial support from Novocure, and his institution received fees from Celgene, Novartis, AbbVie, Merck KGaA (Darmstadt), and MSD-Merck & Co. Dr Stupp's spouse is a full-time employee of Celgene. No other conflicts were reported.

**Funding/Support:** The study was funded by Novocure Ltd.

**Role of the Funder/Sponsor:** Novocure Ltd had a role in the design and conduct of the study; collection, management, and analysis of the data; and decision to submit the manuscript for publication. The study was designed by Drs Stupp and Ram, together with representatives from Novocure, mainly Dr Kirson. The study oversight was supported and monitored by a clinical research organization, which also held the database. Data were collected by the investigators and monitored by the clinical research organization. The statistical analysis plan for the quality of life analyses was developed by Drs Taphoorn, Dirven, Kirson, and Lavy-Shahaf, the sponsor's statistician. Data interpretation was the responsibility of Drs Taphoorn, Dirven, Kirson, and Stupp. The first draft of this manuscript was developed by Drs Taphoorn, Dirven, Kirson, and Stupp. A subsequent mature draft and prefinal version were circulated among all authors who gave additional input, contributed to, and approved the manuscript. The decision to publish the data and its interpretation was made by Drs Stupp and Ram and was supported by all coauthors.

**Meeting Presentation:** This research was presented as a late-breaking oral presentation at the 2017 American Society for Radiation Oncology Annual Meeting; September 24, 2017; San Diego, California.

**Additional Contributions:** We thank the patients and their families for participating in the trial. We

are grateful to all study investigators, nurses, and supporting staff for providing care to the patients and data management.

**Additional Information:** The study oversight was supported and monitored by a clinical research organization that also held the database. The clinical research organization varied among countries and each was paid by Novocure Ltd.

## Abstract

**Background** Tumor treating fields (TTFields) is a non-invasive, antimitotic therapy. In the EF-14 phase 3 trial in newly diagnosed glioblastoma, TTFields plus temozolomide (TTFields/TMZ) improved progression free (PFS) and overall survival (OS) versus TMZ alone. Previous data indicate a  $\geq 75\%$  daily compliance improves outcomes. We analyzed compliance data from TTFields/TMZ patients in the EF-14 study to correlate TTFields compliance with PFS and OS and identify potential lower boundary for compliance with improved clinical outcomes.

**Methods** Compliance was assessed by usage data from the NovoTTF-100A device and calculated as percentage per month of TTFields delivery. TTFields/TMZ patients were segregated into subgroups by percent monthly compliance. A Cox proportional hazard model controlled for sex, extent of resection, *MGMT* methylation status, age, region, and performance status was used to investigate the effect of compliance on PFS and OS.

**Results** A threshold value of 50% compliance with TTFields/TMZ improved PFS (HR 0.70, 95% CI 0.47–1.05) and OS (HR 0.67, 95% CI 0.45–0.99) versus TMZ alone with improved outcome as compliance increased. At compliance  $> 90\%$ , median survival was 24.9 months (28.7 months from diagnosis) and 5-year survival rate was 29.3%. Compliance was independent of gender, extent of resection, *MGMT* methylation status, age, region and performance status (HR 0.78;  $p=0.031$ ; OS at compliance  $\geq 75\%$  vs.  $< 75\%$ ).

**Conclusion** A compliance threshold of 50% with TTFields/TMZ correlated with significantly improved OS and PFS versus TMZ alone. Patients with compliance  $> 90\%$  showed extended median and 5-year survival rates. Increased compliance with TTFields therapy is independently prognostic for improved survival in glioblastoma.

## Introduction

Glioblastoma (GBM) is the most common and aggressive adult brain tumor, accounting for 56% of all gliomas and 15% of all primary brain tumors with an annual incidence in the United States that increases with age—ranging from 0.2 per 100,000 in 0–19 year old population to the highest rate of 15.3 per 100,000 in the 75–84 year old population [1]. Glioblastoma remains incurable with a median survival of only 15 months until recently [2]. The previous standard treatments for newly diagnosed GBM include maximally safe surgical resection followed by radiation therapy (RT) and adjuvant temozolomide (TMZ) chemotherapy [3].

Tumor treating fields (TTFields) are a unique treatment modality [4, 5] for GBM that affects rapidly dividing glioma cells through the action of low-intensity, intermediate

frequency (200 kHz) alternating electric fields [6–9] that act on microtubules and septin fibers of proliferating cancer cells to disrupt mitosis, inducing mitotic cell death, mitotic catastrophe, and cellular stress characterized by autophagy, and endoplasmic reticulum stress [6–13]. TTFields inhibit DNA damage repair by the expression of DNA repair genes in the BRCA1 pathway [14] and impair cellular migration and invasion [15]. TTFields increases cell death when combined with anti-PD1, chemotherapy and radiotherapy [16–19].

The phase 3 EF-11 study of TTFields in recurrent GBM demonstrated comparable efficacy to best physician choice chemotherapy without treatment limiting systemic adverse effects [20]. Post hoc analysis of the EF-11 trial data showed significantly longer median OS with TTFields at compliance rate of  $\geq 75\%$  ( $\geq 18$  h daily) versus those with a  $< 75\%$  compliance rates [21] and high compliance rates of  $> 90\%$  with EF-11 responders [22]. The Patient Registry Dataset (PRiDe) showed significant improvement in median OS at daily compliance rates of  $\geq 75\%$  versus  $< 75\%$  [23]. The phase 3 EF-14 study in newly diagnosed GBM demonstrated that TTFields plus maintenance TMZ therapy significantly improved PFS and OS without decline in health related quality of life (HRQOL) versus TMZ alone [24–26]. The National Comprehensive Cancer Network (NCCN) has recently (2018) recommended TTFields with TMZ as a standard Category 1 treatment option for newly diagnosed GBM [27].

Unlike systemic therapies, TTFields are only active against cancer cells while the transducer arrays are placed on the scalp and the field generator is continuously administering alternating electric fields of a specific intensity (200 KHz) for GBM. There are no peak-trough fluctuations or half-life associated with TTFields. The specificity of TTFields on anti-mitotic activity of rapidly dividing glioma cells, while sparing normal cell division, enables near continuous cancer therapy with minimal systemic adverse effects. Therefore, active compliance with TTFields therapy is a critical parameter for clinical benefit.

The objective of this subgroup analysis of the EF-14 phase III trial data was to analyze compliance data to correlate TTFields compliance with PFS and OS and identify potential lower boundary for compliance rates with improved clinical outcomes.

## Methods

This subgroup analysis is based on TTFields plus TMZ and TMZ alone patient data from the EF-14 study [24]. The EF-14 trial was a randomized, open-label trial, which enrolled 695 newly diagnosed patients with GBM whose tumor was either resected or biopsied and had also

completed concomitant radiation therapy with adjuvant TMZ therapy. Patients were randomized 2:1 to TTFields plus maintenance TMZ chemotherapy ( $n=466$ ) or temozolomide alone ( $n=229$ ). Temozolomide was administered to both groups (150–200 mg/m<sup>2</sup>) for 5 days per 28-day cycle (6–12 cycles). The median time from diagnosis to randomization in both groups was 3.8 months [24].

The primary outcome of this subgroup analysis was to assess the percentage of monthly TTFields compliance as an independent predictor of PFS and OS compared with patients in the TMZ alone treatment group. Compliance data are derived from the internal computerized log file of each NovoTTF-100A (Optune®) device. Percent of the total treatment time during which the NovoTTF-100A treated patients actually received treatment was calculated by analyzing the log file of each device and dividing the total device ‘ON’ time by the prescribed number of 1 month treatment courses.

Patient compliance was calculated as the average percentage of each month the system was delivering TTFields. Progression-free survival and OS data from the TTFields plus TMZ treated group were analyzed in subgroups based on monthly compliance levels of  $< 75\%$  or  $\geq 75\%$  and finer monthly compliance bins of 0 to  $\leq 30\%$ , 30% to  $\leq 50\%$ , 50% to  $\leq 60\%$ , 60% to  $\leq 70\%$ , 70% to  $\leq 80\%$ , 80% to  $\leq 90\%$ , 90% to  $\leq 100\%$ .

The PFS and OS survival curves were constructed using the Kaplan–Meier method. Cox proportional hazards model was used to analyze treatment compliance as an independent predictor of survival controlling for treatment group, sex, *MGMT* methylation status, resection status, Karnofsky Performance Status (KPS) and country of residence (United States versus outside the United States). The threshold for significant interactions in the model was specified at an  $\alpha$  of 0.05.

## Results

In the EF-14 study, 466 patients were randomized to the TTFields plus TMZ therapy group and 229 were randomized to the TMZ alone group [24]. The patient disposition is shown in Supplementary Fig. 1. In summary, for the TTFields plus TMZ group—the majority of patients were men (68%) with a median age of 56 years, and a KPS of 90% [24]. The *MGMT* promoter region was unmethylated in 54% and methylated in 36% patients in the TTFields plus TMZ group [24]. Table 1 shows the baseline demographic characteristics of the TTFields plus TMZ group separated into subgroups based on percent compliance. Overall, the separate percent compliance groups were matched in baseline characteristics both with each other and the full data set of the primary study.

**Table 1** Baseline demographics by TTFields percent average daily compliance

% Compliance	0 to ≤30 (n=22)	30 to ≤50 (n=40)	50 to ≤60 (n=42)	60 to ≤70 (n=46)	70 to ≤80 (n=91)	80 to ≤90 (n=166)	90 to ≤100 (n=43)	TMZ alone (n=229)
Median age, years (range)	55.5 (30–70)	57.5 (25–78)	54.5 (22–79)	55.0 (20–83)	56.0 (30–78)	56.0 (28–80)	52.0 (19–68)	57.0 (19–80)
KPS, median (range)	80.0 (70–100)	90.0 (70–100)	90.0 (70–100)	90.0 (60–100)	90.0 (70–100)	90.0 (70–100)	90.0 (70–100)	90.0 (70–100)
Extent of resection, n (%)

MGMT tissue available and tested, n (%)	16 (73)	34 (85)	39 (93)	35 (76)	71 (78)	142 (86)	37 (86)	185 (81)
Methylated	5 (31.3)	14 (41.2)	12 (30.8)	13 (37.1)	24 (33.8)	49 (34.5)	15 (40.5)	77 (41.6)
Unmethyl- ated	10 (62.5)	15 (44.1)	24 (61.5)	20 (57.1)	41 (57.7)	76 (53.5)	17 (45.9)	95 (51.4)
Invalid	1 (6.3)	5 (14.7)	3 (7.7)	2 (5.7)	6 (8.5)	17 (12.0)	5 (13.5)	13 (7.0)

Analysis of the more refined rates of compliance (smaller bin sizes) shows a trend in favor of longer PFS and OS with progressively higher levels of monthly compliance. A threshold value of  $\geq 50\%$  average monthly compliance with TTFields plus TMZ (Fig. 1) was needed to show an extension of PFS (HR 0.70, 95% CI 0.47–1.05) and OS (HR 0.67, 95% CI 0.45–0.99) compared to TMZ alone. Both PFS and OS were extended when compliance was increased beyond 50%, indicating progressively increased gains in PFS and OS as compliance increases.

Patients with TTFields plus TMZ compliance levels of  $> 90\%$  showed maximum survival benefits (Fig. 2), with a

median PFS of 8.2 months for the TTFields plus TMZ group compared to 4.0 months in the TMZ alone group (HR 0.538, 95% CI 0.365–0.794;  $p=0.0047$ ) and an OS of 24.9 months (28.7 months from diagnosis since time from diagnosis to randomization was 3.8) in the TTFields plus TMZ arm compared to 16.0 months in the TMZ alone group respectively (HR 0.522, 95% CI 0.347–0.787;  $p=0.0007$ ). TTFields plus TMZ treated patients with  $> 90\%$  compliance rate had a 5-year survival rate of 29.3% (Fig. 3).

A compliance level of  $\geq 75\%$  monthly duration of treatment with TTFields plus TMZ was an independent predictor of OS, as was methylated *MGMT* status, age and KPS

### Progression-Free Survival

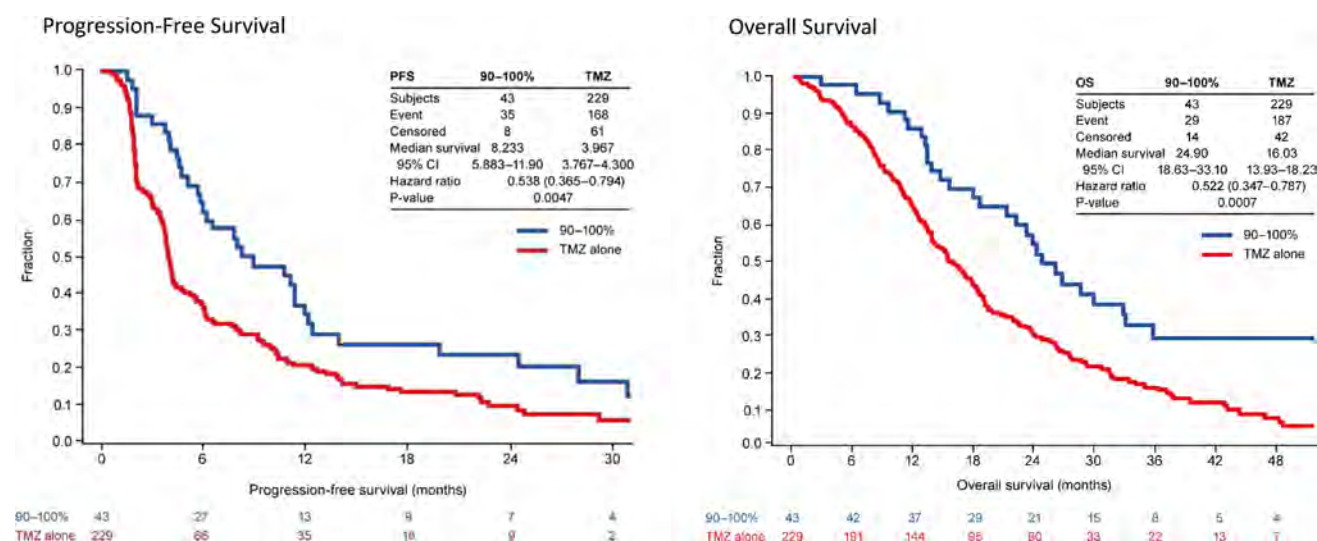

### Overall Survival

**Fig. 1** Forest plots show the effect of treatment compliance with TTFields plus TMZ on PFS and OS. A threshold value of 50% compliance with TTFields plus TMZ was needed to show a significant extension of OS compared to TMZ alone. Both PFS and OS were

extended with treatment compliance levels  $> 50\%$ . A trend in favor of longer PFS and OS was seen with higher rates of treatment compliance

**Fig. 2** Newly diagnosed GBM patients had maximal treatment benefit from TTFields plus TMZ with compliance rates >90% with a median overall survival of 24.9 months (28.7 months from diagnosis)

**Fig. 3** The annual survival rate was highest for newly diagnosed GBM patients with compliance rates >90% with a 29.3% survival rate over 5 years from randomization

(Table 2) regardless of treatment arm (reference values—compliance <75%), sex (male), resection (biopsy), *MGMT* (negative), and region (USA).

## Discussion

In this subgroup analysis of EF-14 study patients receiving TTFields plus TMZ treatment, a threshold value of  $\geq 50\%$  average compliance with TTFields plus TMZ showed an extension of PFS and OS compared to TMZ alone. Further, patients with monthly compliance >90% had maximal survival benefit with a median survival of 24.9 months (28.7 months from diagnosis) and a 5-year survival of 29.3%. This effect was independent of other prognostic factors such as performance status, age, and *MGMT* methylation status.

**Table 2** Cox proportional hazards model for OS in TTFields/TMZ patients

Parameter	Parameter value	Hazard ratio	Two-sided p-value
Treatment arm	Compliance $\geq 75\%$	0.781	0.031
Sex	Female	0.800	0.069
Resection status	Gross total resection	0.789	0.202
	Partial resection	0.777	0.181
MGMT status	Methylated	0.510	<0.001
	Unknown	0.810	0.131
Region	Outside the USA	1.157	0.199
Age		1.021	<0.001
KPS		0.984	0.006

Compliance was an independent predictor of OS in the full 5-year dataset ( $\geq 75\%$  vs. <75%) [24].

Post hoc analysis of the EF-11 trial data demonstrated longer median OS in TTFields treated recurrent GBM patients with a compliance rate of  $\geq 75\%$  compared to those with a <75% compliance rate (7.7 vs. 4.5 months;  $p=0.042$ ) [21]. This early analysis supported a preliminary target level for treatment compliance ( $\geq 75\%$ ) in clinical practice as well as evidence for a trend suggesting that higher levels of survival benefit were associated with increasing compliance [21]. Data from the PRiDe registry—using data from real-world recurrent GBM patients—also demonstrated improved OS with daily compliance rates  $\geq 75\%$  [23]. The results of the EF-14 sub-group analysis further support a threshold compliance rate of  $\geq 75\%$  for a survival benefit when compared to a compliance rate of <75% in newly diagnosed

GBM patients treated with TTFields plus TMZ. This study demonstrates that a minimal compliance threshold of > 50% with TTFields plus TMZ treatment correlated with significantly improved survival outcomes compared to TMZ alone for newly diagnosed GBM. TTFields were administered to GBM patients with recurrent disease as monotherapy in the EF-11 study and as combination therapy with TMZ in newly diagnosed GBM patients in the EF-14 study. The earlier disease stage and combined treatment may account for the survival benefits seen at a lower minimal compliance threshold in this subgroup analysis of the EF-14 study.

A variety of social and clinical factors contribute to patient compliance with TTFields therapy. Though TTFields are non-invasive and the Optune device is designed to preserve patient functioning during daily activities, initiating TTFields therapy requires some lifestyle modifications when compared to RT or systemic therapies. Some patients may be reluctant to comply with the head shaving required with every array change and wearing the arrays on a shaved head may make some patients self-consciousness, calling attention to their condition [28]. Healthcare providers experienced with TTFields therapy can provide patients assistance with incorporating the therapy in their daily life [28].

TTFields, like oral cancer treatment regimens, are administered in the home and outpatient setting and places the burden of compliance on the patient and their caregivers. Patient, healthcare provider, and treatment related factors can contribute to improved adherence or compliance with oral cancer therapy regimens [29]. Patient related factors include physical limitations, psychological, and social issues such as religious or cultural factors and the lack of a support system. The healthcare provider can also negatively influence compliance with therapy through poor communication and relationship with the patient, as well as failing to optimally select appropriate patients for oral cancer therapy regimens [29].

A good home support system is critical when considering TTFields therapy for a GBM patient [28]. A patient should have at least one support person who can assist with the Optune device operation, assist with managing adverse events, scalp maintenance and array placement. Patients with cognitive issues or poor performance status have been suggested to be more likely to be less compliant with TTFields treatment without home support [28]. However, the current study showed compliance to be independent of KPS and age as a predictor of PFS and OS, contradicting this suggestion. Treatment-related factors influencing compliance include complex treatment regimens, concomitant treatments and side effects. TTFields are not associated with systemic side effects and are less likely to affect concomitant systemic therapy.

The most common side effect in clinical trials was skin irritation for patients treated with TTFields [20, 24, 25].

Dermatological adverse events were the most common adverse events associated with TTFields; 52% of TTFields plus TMZ patients in the EF-14 trial reported mild to moderate skin irritation [24]. Skin irritation is due primarily to the nearly continuous contact of the transducer arrays with the patients shaved scalp between array changes. These events include allergic and irritant dermatitis, mechanical lesions, ulcers and skin lesions [30]. However, most of these dermatological AEs can either be prevented with proper shaving techniques, skin care and array relocations, or treated with appropriate topical regimens as required [30]. Effective skin care strategies can maximize compliance with TTFields therapy and maintain patient QoL over the course of treatment.

A limitation of this study is that it is based on a subgroup analysis of the phase 3 EF-14 trial, and inherently subgroup analyses are prone to type I errors limiting the veracity of the results [31]. In this instance, the subgroup analysis was prespecified in the protocol. However, the results of this investigation corroborate the results of similar analyses of prior clinical investigations [21–23].

## Conclusions

In this subset analysis of the EF-14 trial, a compliance threshold of 50% with TTFields plus TMZ treatment correlated with significantly improved outcomes compared to TMZ alone. Higher levels of treatment compliance with TTFields plus TMZ were associated with increased durations of progression free- and overall-survival suggesting a dose response mechanism for TTFields. This effect was independent of other prognostic factors such as performance status, age, and *MGMT* methylation status. Patients with compliance over 90% had a median survival of 24.9 months (28.7 months from diagnosis) and a 3-, 4-, and 5-year survival of 29.3%. This plateau effect on long term survival has been identified in other GBM treatments which have known immunologic mechanisms of action [32, 33]. The importance of compliance with TTFields therapy in real world clinical settings should be strongly conveyed to patients by their treating physicians and other allied healthcare providers.

## Practice Points

- Tumor treating fields (TTFields) in combination with temozolomide are a standard treatment option in patients newly diagnosed with glioblastoma (GB) following maximal surgical debulking and completion of concurrent chemoradiation.
- Treatment planning using the NovoTAL software optimizes TTFields intensity delivered in two orthogonal directions to the gross tumor volume and the proximal peritumoral brain zone.
- Sequential neuroimaging should be reviewed in order to assess the extent of active, residual enhancing and nonmeasurable tumor when performing treatment planning.
- Treatment should be planned mapping closely to the boundaries of active tumor or to the margins of a resection cavity visualized in axial and coronal planes using T1 postcontrast or T2/fluid-attenuated inversion recovery sequences as appropriate.
- Changes in neuroimaging can occur following the initiation of treatment with TTFields. Response assessment should incorporate a comprehensive evaluation of the patient's clinical status, concurrent therapies received, treatment compliance and general scalp health when assessing clinical response.
- The median duration of TTFields therapy in a pivotal Phase III study conducted in newly diagnosed GB patients was 9 months, with patients remaining on TTFields with a change to second-line chemotherapy through first progression.
- Treatment can be re-planned if there are significant changes in imaging from baseline.
- The development of TTFields treatment planning and response assessment algorithms aim to help standardize patient care across specialties and institutions caring for patients with GB.

Tumor treating fields (TTFields) are an integral treatment modality in the management of glioblastoma and extend overall survival when combined with maintenance temozolomide in newly diagnosed patients. Complexities exist regarding correct selection of imaging sequences with which to perform TTFields treatment planning. Guidelines are warranted first, to facilitate treatment planning standardization across medical disciplines and institutions, to ensure optimal TTFields delivery to the tumor and peritumoral brain zone while maximizing

patient safety, and also to mitigate the risk of premature cessation of a potentially beneficial treatment. This summary guideline outlines methods for starting patients on TTFields, for monitoring patient response to therapy and provides a framework for evaluating when therapy should be re-planned, based on the extent of sequential imaging changes.

## Background

Tumor treating fields (TTFields) are an integral modality in the management of patients with newly diagnosed and recurrent glioblastoma (GB), in addition to surgery, radiation and chemotherapy. TTFields are a regionally delivered treatment utilizing alternating electric fields to disrupt highly orchestrated intracellular processes necessary for successful cell division [1–5]. TTFields are clinically delivered in paired orthogonal directions, left–right and anterior–posterior, using Optune™ (NovoTTF-100A System). Optune is a portable medical device consisting of a TTFields generator, custom backpack and insulated ceramic discs called transducer arrays, which are applied directly to a patient's shaved scalp (Supplementary Figure 1) [6,7]. The device is preset to deliver TTFields at a frequency of 200 kHz and is operated by the patient independently. It is monitored periodically by device specialists, who are available 24/7 to provide technical support to the patient, their family and physician.

TTFields are nonionizing and are delivered at an intermediate frequency (200 kHz for GB) and low intensities (1–3 V/cm) leading to a variety of downstream, antimitotic biologic effects, sparing quiescent cells. These include disruption of normal mitotic spindle and cytokinetic contractile band assembly [1,4], mitotic arrest [8], dielectrophoresis of charged intracellular macromolecules during cytokinesis [9,10], which ultimately result in polyploidy and aneuploidy in cellular progeny, leading to a loss of clonogenic potential [4,11,12], and immunogenic cell death [13]. When applied to GB cell lines in *in vitro* studies, TTFields can also induce other stress effects potentially culminating in the activation of immune-mediated and other death pathways [4,11,14]. In addition, TTFields have also been shown to induce autophagy, and can modulate cellular propensity to migrate and invade adjacent tissues [15,16]. Preclinical studies in GB and other cancer cell lines demonstrate that incremental cytotoxic effects can be

observed when TTFields' intensity is increased from 1 to 2–3 V/cm, with complete arrest of cellular proliferation observed with field intensities exceeding 2.25 V/cm [1,5]. TTFields exert maximal effects when aligned to a cell's mitotic axis. As a cell's mitotic axis can occur randomly in any direction, additive cytotoxic effects are also observed when TTFields are applied in multiple sequential directions [5].

Although the direct measurements of TTFields intensities delivered to the brain are not performed routinely, advanced electric field simulation studies can provide insights into the behavior and distribution of TTFields in the clinical setting. Spatial distributions of electric fields within the brain parenchyma have been determined in realistic head models computed with finite element method (FEM) simulations [17,18]. Image segmentation initially separates major tissue types such as scalp, skull and gray and white matter using MRI sequences and then model transducer arrays are positioned directly on the scalp [18]. The dimensions and separation of model electrodes accurately represent the geometry of ceramic discs used clinically. Volume meshes are generated and solved using the FEM framework with preset electric field parameters of 200 kHz, and isotropic tissue conductivity and relative permittivity values. A corresponding electromagnetic wavelength for a propagating field at a similar frequency would be on the order of 1 km. As TTFields are applied across the head at much shorter distances (~20–30 cm), it is not possible to precisely focus the field to target discrete structures, as is possible with radiosurgery. Instead, TTFields will distribute nonuniformly mainly throughout the supratentorial brain. Electric field intensities can differ significantly based on the heterogeneous dielectric tissue properties of cranial structures such as the gray matter, white matter tracts and cerebrospinal fluid [17–19], tumor location, tumor properties and transducer array layout [20]. As the majority of GB will recur at the margin of a resection cavity or within the proximal 20 mm

of peritumoral brain zone (PBZ) to the original tumor bed [21-23], it is important to understand the distribution of TTFields in these regions. Recent simulation studies have shown that electric field intensity delivered to the gross tumor volume (GTV) and proximal PBZ exceeds therapeutic thresholds of 1 V/cm in both orthogonal directions for models with solid brain tumors (Supplementary Figure 2) [24].

In clinical practice, TTFields are indicated in combination with maintenance temozolomide (TMZ) for the treatment of patients with newly diagnosed GB, and as monotherapy for patients with recurrent disease [25,26]. TTFields gained US FDA approval for newly diagnosed GB patients based on the positive results of the Phase III randomized controlled, EF-14 study [25]. At the first prespecified interim analysis, this trial demonstrated that 315 patients with newly diagnosed GB (who had undergone maximal surgical debulking followed by six cycles of concurrent chemoradiation), randomized 2:1 to receive TTFields with maintenance TMZ, experienced a significantly longer median progression-free survival (PFS) and median overall survival (OS) compared with patients receiving maintenance TMZ alone (20.5 vs 15.6 months; hazard ratio [HR]: 0.64;  $p = 0.004$ ). The addition of TTFields to standard of care did not increase serious adverse events and did not impair performance status or quality of life [27]. In the EF-14 study, patients randomized to the TTFields/TMZ treatment arm could remain on TTFields at first progression and switch to second-line chemotherapy [25]. In a *post hoc* analysis, OS was significantly higher from first progression, in patients receiving TTFields in combination with second-line chemotherapy compared with patients receiving second-line chemotherapy alone (11.8 vs 9.2 months; HR: 0.695;  $p = 0.0489$ ) [28]. TTFields were originally approved in the recurrent GB setting as monotherapy, based on the results of the randomized controlled Phase III, EF-11 study [26]. This randomized trial demonstrated equivalent efficacy (median OS: 6.6 vs 6.0 months; HR: 0.86;  $p = 0.27$ ) combined with improved safety and quality of life in patients receiving TTFields monotherapy compared with patients receiving best physician's choice of chemotherapy [26]. As TTFields are a locally directed therapy with no half-life, systemic side effects observed with chemotherapy are not typically seen in patients receiving TTFields monotherapy. The most

common treatment-related adverse events are dermatologic in nature and have been reviewed in detail previously [29]. Skin irritation can occur beneath the transducer arrays as a consequence of chemical irritation from the hydrogel, local moisture at the skin surface or due to allergic irritation in response to the hydrogel and adhesive tape. In addition, as treatment requires shaving of the scalp and replacing the transducer arrays two- to three-times per week, mechanical trauma from repeat shaving and physical stresses from removal and reapplication of the arrays can also predispose the skin to erosions. Pressure from the ceramic transducer discs can lead to decreased skin perfusion, a risk that is exacerbated in the presence of scars, hardware and in patients who have received prior radiation therapy. In some cases, this can lead to the development of an ulcer. Inappropriate scalp care can also lead to skin infections and folliculitis. The majority of dermatologic adverse events are mild to moderate in nature and can be managed with high-potency topical steroids or topical antibiotics without requiring breaks in treatment. Grade 3/4 adverse events were observed in 2% of patients receiving TTFields monotherapy in the EF-11 trial [26]. The TTFields device is contraindicated in patients with active implanted electronic medical devices such as deep brain stimulators, pacemakers and programmable shunts, and in patients with skull defects such as a missing bone flap, due to the risk of skin toxicity and tissue damage. It should also not be used in patients with known hypersensitivity to conductive hydrogels or in patients with infratentorial disease.

In order to maximize the intensity of electric field delivered at the site of active tumor, treatment is individualized for each patient using the Novocure Transducer Array Layout – NovoTAL™ System (NovoTAL) [30]. In simulation studies, personalizing treatment results in near doubling of TTFields intensity delivered to the GTV compared with TTFields delivery using a default symmetric array layout [20]. Treatment planning with NovoTAL is required for any patient commencing treatment with TTFields. In the clinical trial setting, treatment planning was historically performed by the study sponsor's clinical team using the patient's baseline MRI results. In the clinical practice setting, physicians certified to prescribe TTFields who are managing patients with GB, may elect to perform their own treatment planning by

completing a NovoTAL certification program, presently only available in the USA. This program provides education on the fundamental principles of electric field distribution theory and practical training on obtaining head morphometric measurements, as well as tumor coordinates from MRI scans. A basic requirement for this certification is that physicians have familiarity with reading and interpreting neuroimaging. As the treating physician may have comprehensive information regarding the patient's clinical history, current clinical status and knowledge of sequential imaging changes, there, may be potential benefits for the patient(s) in having their treating physician plan therapy directly.

#### • Overview of TTFields treatment planning using NovoTAL

Conventional treatment mapping using the FDA-approved NovoTAL software [30] is performed by planning treatment to the extent of contrast-enhancing disease most indicative of active tumor (methods described previously) [30–33]. A measure of axial head size is first obtained using the image at the uppermost limit of the orbit on a T1-weighted sequence (Figure 1A). A fiducial frame is placed around the head bordering the outer margin of the scalp on four sides. Measurements for anteroposterior (A-P), right-to-left (R–L) and right to anatomic midline distances are obtained from the level of the scalp, extending tangentially from a right-anterior marker origin. Coronal head size is assessed in a similar manner, using a box drawn around the head to the lower margin of cerebrum on an MRI image at the level of the external auditory canal (Figure 1B). Conventional tumor location measurements are obtained from T1-weighted postcontrast sequences in axial and coronal views, selecting images that contain the maximal diameter of contrast enhancement. Boxes are drawn around the head commencing at the outer margin of the scalp axially and encompassing the extent of supratentorial cerebrum coronally. The same measurements described previously (anteroposterior, R–L and right to midline) are obtained (Figure 1C & D). In addition, four measures for tumor coordinates are obtained commencing from the reference frame and from a right-anterior or right-superior origin, respectively. On axial views, these are measurements from the right reference frame to the near tumor margin and to the far tumor margin, and the distance from the front of the

reference frame to the near tumor margin and to the far tumor margin. On the coronal slice capturing the maximal diameter of contrast enhancement, the four tumor coordinates are measured from the right reference frame to near tumor margin and to the far tumor margin, and from the top of the reference frame to the near tumor margin and to the far tumor margin. All measurements are rounded to the nearest millimeter and are entered sequentially into the NovoTAL software. Based on the data derived from FEM simulations, the software algorithm will calculate the optimal transducer array layout, which will maximize TTFields intensity at the site of the tumor based on the patient's cranial morphometry.

Although the process described above is based on MRI measurements obtained from postcontrast imaging, in the clinical setting gliomas can be very heterogeneous in nature, and thus the extent of active disease may not exclusively be captured in postcontrast sequences [34–36]. GBs may present with non-CE (NCE) T2-weighted/fluid-attenuated inversion recovery (FLAIR) signal, or more commonly may be represented in a combination in contrast-enhancing and NCE frames. A patient will minimally require an MRI with T1-weighted, T2-weighted/FLAIR and gadolinium-enhanced sequences in axial and coronal planes for treatment planning. A combination of these sequences can be used for planning purposes, as deemed appropriate by the treating physician. Although mapping based on discrete regions of contrast enhancement may result in a more focal planning approach, incorporation of margins of macroscopically normal brain or of wider regions of T2/FLAIR abnormality can alter the intensity of TTFields in areas where GB most commonly recurs such as the GTV, tumor margin and PBZ [21]. Maximizing field intensity within these zones could prove to be crucial for prolonging PFS and for improving patient outcomes overall. The PBZ, which macroscopically and radiologically resembles normal tissue, frequently harbors infiltrating tumor cells, tumorigenic stromal cells and pro-inflammatory cells, which collectively support local tumor recurrence [22]. As such, a physician may theoretically wish to include a wider margin on NCE tissue into the treatment plan for TTFields in order to treat residual infiltrating tumor cells. Results of treatment planning simulation studies exploring the inclusion of a margin of macroscopically normal tissue around

**Figure 1. Standard T1-weighted postcontrast MRI measurements required to perform NovoTAL treatment planning.** (A) An axial slice at the apical level of the orbit. A reference frame is drawn at the level of the scalp, and measurements for anteroposterior, left-right and right to midline are drawn. (B) A coronal slice at the level of the external auditory canal used to estimate the extent of cerebrum. A reference frame is drawn from the level of the scalp to an inferior boundary at the lower extent of temporal lobe, and measurements for right-left, right to midline and superior to inferior boundary are obtained. (C) Axial tumor coordinates drawn on a slice demonstrating the maximal tumor diameter. The same frame and initial measurements are repeated. In addition, measurements from the right frame to near and far tumor margins, as well as the anterior frame to near and far tumor margins, are added. (D) Coronal tumor coordinates drawn on a slice depicting the maximal diameter of tumor. The lower boundary of the box is drawn at the lowest level of visible supratentorial brain. The three initial head size measurements are repeated. In addition, measurements from the right frame to the near and far tumor margins, and from the top of the frame to the near and far tumor margin are obtained.

a boundary of contrast-enhancing tumor suggest that field intensity is optimized in the GTV and PBZ, when treatment is planned mapping

to the border of contrast-enhancing disease, as opposed to mapping to include wider margins of NCE PBZ. As such, this guideline recommends

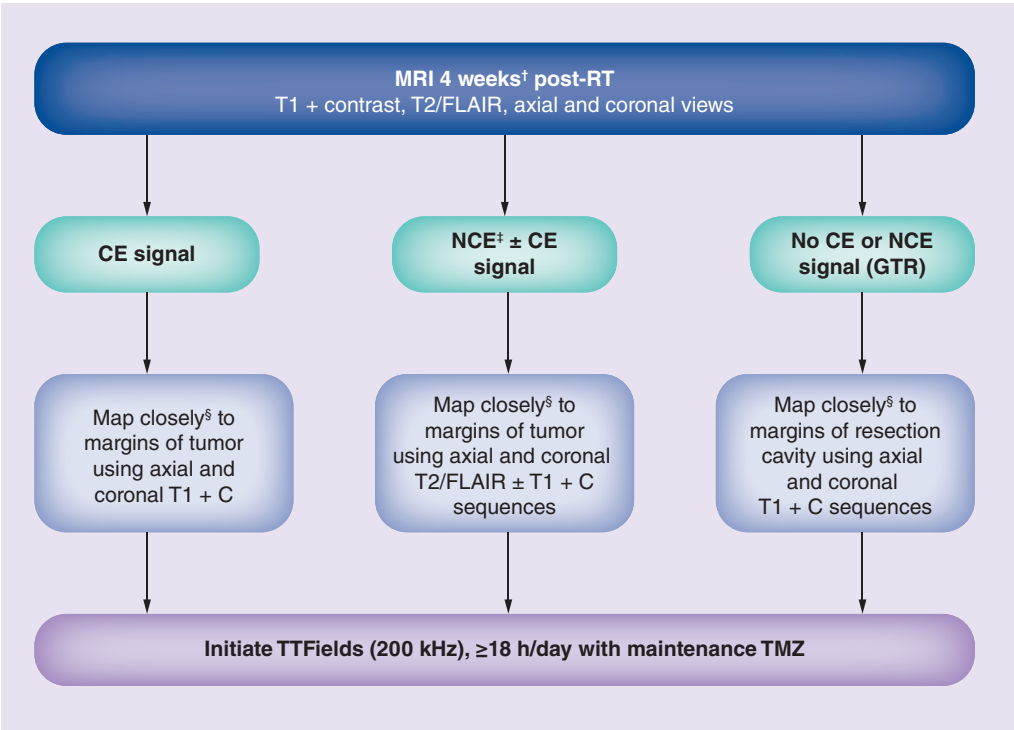

planning therapy as closely as possible to the margins of areas representing active tumor.

• **Treatment planning for newly diagnosed GB**

In the newly diagnosed setting, an MRI performed approximately 4 (range: 2–6) weeks following completion of chemoradiation should be used for TTFields treatment planning purposes. However, supplemental information from the preoperative, postoperative and preradiation therapy scans (when available) can also help inform the region most likely to represent residual active tumor and target any microscopic disease. The minimum MRI sequences required are precontrast T1, T2/FLAIR and postcontrast T1 (axial and coronal), and the recommended

slice thickness is  $\leq 5$  mm with no gap. In rare instances, where a patient cannot undergo MRI, a CT scan with contrast can be used for treatment planning, as long as axial and coronal head size and tumor position can be clearly delineated. **Figure 2** describes the algorithm for treatment planning in patients with newly diagnosed with GB.

In the postradiation setting, an important consideration is to distinguish post-treatment imaging changes such as pseudoprogression [37,38] from true disease progression. As mentioned previously, field intensity will be maximized in the GTV and PBZ, when the field is mapped as closely as possible to the margin of active tumor, so care should be taken not to overestimate the extent of active residual tumor. As reactive

**Figure 2. Tumor treating fields treatment planning algorithm for newly diagnosed glioblastoma.**

<sup>†</sup>MRI obtained 2–6 weeks following completion of concurrent chemoradiation is recommended for treatment planning in patients with newly diagnosed GB. Where available, compare preoperative and pre-RT sequences to determine areas of active disease versus post-treatment sequelae.

<sup>‡</sup>In instances where a newly diagnosed patient has exclusively NCE signal, mapping should be performed using axial and coronal T2/FLAIR images, closely approximating to the margins of the tumor.

<sup>§</sup>Coordinates for tumor location should closely approximate the edge of the region most representative of active tumor without including extra margin of normal tissue. This approach will maximize the field intensity in both the tumor volume and proximal peritumoral brain zone.

**Figure 3. Treatment planning in patient post gross total resection with no evidence of residual disease.** (A–C) (from top left to right) Post-radiotherapy axial views on fluid-attenuated inversion recovery, T1 and T1 with contrast sequences for a patient post-gross total resection. Head size measurements are obtained as standard on slices at the apical level of the orbit on axial views and at the level of the auditory canal on coronal views (not shown). (D & E) Treatment planning to the boundaries of the resection cavity on axial and coronal views, respectively. On axial views, the reference frame is drawn around the head, excluding the nose anteriorly. On coronal slices, the reference frame is drawn at the level of the scalp, excluding the ears, and the inferior margin is drawn to the lowest level of visible tentorium.

alterations in the blood–brain barrier with contrast enhancement may mimic tumor progression, there may be clinical value in obtaining additional imaging such as a magnetic resonance perfusion or PET scan in order to determine which areas represent active tumor [39–41]. For patients who have undergone a gross total resection and have neither residual contrast-enhancing nor NCE signals, treatment planning should be performed mapping as closely to the margins of the resection cavity as possible (Figure 3). The output from the NovoTAL software – the transducer array layout map – should subsequently be

evaluated in the context of any surgical scars, impaired skin or palpable hardware that may impact the application of the transducer arrays on the patient’s scalp. TTFields are contraindicated in patients with skull defects where the bone was not replaced and the arrays should not be placed directly above any palpable hardware, screws or underlying serious skin condition. A slight shifting of the arrays is appropriate in such instances.

In patients who have undergone biopsy or subtotal resection (those with residual tumor), sequential scans should be reviewed to determine

the areas that represent most active areas of tumor. Mapping should be performed using the postcontrast and/or T2/FLAIR sequences as appropriate. The size of the planning field should conform to the boundary of active tumor, avoiding and excluding blood products or cystic cavities not surrounded by active tumor, in order to optimize the field intensity in the tumor volume and PBZ.

#### • Treatment planning for recurrent GB

There are additional practical considerations when planning treatment with TTFields for patients with recurrent GB, again with regard to evaluating and interpreting imaging changes and assessing the effects of prior therapies. Tumor progression can often be challenging to distinguish from pseudoprogression [42] or radiation necrosis. Given the frequent use of bevacizumab in recurrent GB, pseudoresponse should also be carefully evaluated in patients receiving antiangiogenic therapy [37,43-44]. These scenarios can lead to both an over- or under-estimation of active tumor volume in the context of TTFields planning and may lead to suboptimal delivery of TTFields. In this setting, additional information obtained from advanced imaging modalities such as diffusion-weighted imaging, apparent diffusion coefficient maps, magnetic resonance spectroscopy and perfusion-weighted imaging may help correlate regions that represent active tumor and distinguish tumor from pseudoprogression [45,46]. Patient's scalp health should also be carefully evaluated when considering TTFields in the recurrent GB setting. Prior exposure to systemic chemotherapies and radiation may render patients more susceptible to skin toxicity (the most common device-related adverse event reported with TTFields treatment); therefore, regular evaluation of the patient's scalp while receiving therapy can help prevent the development of local skin irritation beneath the transducer arrays [29]. **Figure 4** describes the algorithm for treatment planning in patients with recurrent GB. The most recent MRI scan showing tumor progression should typically be used for TTFields treatment planning in patients with recurrent GB. A careful comparison between prior scans should be made in order to identify the areas of active tumor. This is especially important in patients who have received antiangiogenic therapy, in whom prior imaging (when available) should be evaluated with the most recent scan. Many

patients receiving bevacizumab commonly progress with a nonenhancing signal abnormality and therefore are more likely to require the inclusion of T2/FLAIR sequences in treatment planning. The treating physician should correlate the imaging findings with the patient's clinical status and determine the region where the TTFields should be focused. The mapping coordinates should conform closely to the margin of the active tumor as this will maximize field intensity in the tumor volume and the PBZ (**Figure 5**).

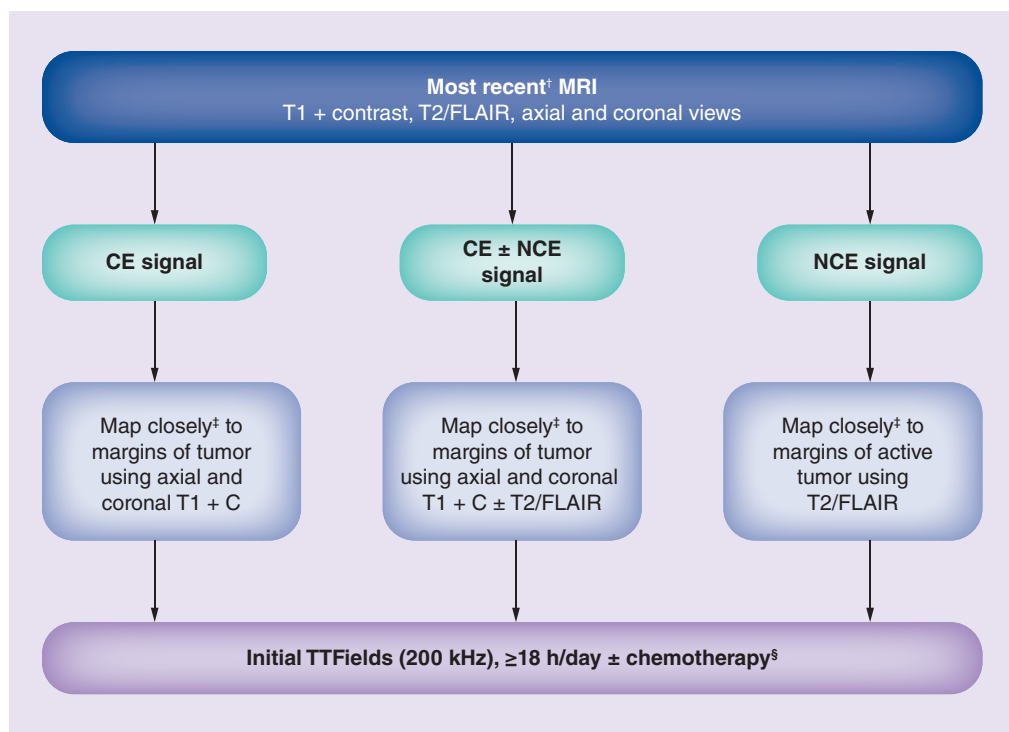

#### • Treatment planning for multifocal GB

Approximately one in five patients with GB may present with multifocal or multicentric disease manifesting with assorted distinct foci of enhancing tumors [47]. TTFields are a viable modality in the treatment of such patients, as TTFields distribute at therapeutic intensities within large areas of the supratentorial brain [17]. The NovoTAL software can accommodate treatment planning for any number distinct lesions (>1 cm apart) within its algorithm. Any lesions which are <1 cm apart should be treated as one contiguous lesion. The approach to planning therapy in cases with multifocal disease is the same as described previously; once measurements for axial as well as coronal head size have been obtained, each lesion should be delineated and measured separately, and the coordinates entered sequentially into the NovoTAL software (**Figure 6**).

#### • Response assessment & remapping TTFields

Once TTFields are initiated, the treating physician should monitor the patient's monthly compliance report to ensure that patient is receiving the maximal benefit from the treatment (the recommended goal is to be on therapy >18 h per day), and should periodically assess the scalp so that any local skin irritation is appropriately managed. A follow-up MRI scan should routinely be performed 2–3 months following treatment start as is the standard practice for GB follow-up. There are unique challenges associated with the ongoing evaluation and interpretation of imaging changes in response to treatment with TTFields, which are compounded by observations from clinical trials suggesting that there is no definitive correlation between objective radiographic response and overall patient benefit. *Post hoc* analyses have

**Figure 4. Tumor treating fields treatment planning algorithm for recurrent glioblastoma.**

<sup>†</sup>Where available, compare pretreatment and post-treatment imaging to determine areas of active disease versus post-treatment sequelae, especially in patients receiving antiangiogenic therapy.

<sup>‡</sup>Coordinates for tumor location should closely approximate the edge of the region most representative of active tumor without including extra margin of normal tissue. This approach will maximize the field intensity in both the tumor volume and the proximal peritumoral brain zone.

<sup>§</sup>Patients initially receiving TTFields with maintenance TMZ who experience first progression, can remain on TTFields with a change to second-line chemotherapy.

demonstrated that tumor regression and clinical benefit can still occur following initial early radiographic progression in patients receiving TTFields [48,49]. In a *post hoc* responder analysis from EF-11 (where TTFields were administered as monotherapy in recurrent GB patients), approximately a third of responders experienced progressive disease on their 2-month scan following initiation of TTFields. However, they subsequently developed delayed (median time to onset of objective response of 8 months), durable (a median duration of 7 months) and objective radiographic responses [48]. Similar observations are noted in patients receiving novel immunotherapeutics [50-52], which have recently prompted the Response Assessment in Neuro-Oncology Criteria (RANO) working group to develop an updated immunotherapy response assessment guideline (iRANO). This new guidance allows patients to remain

on immune therapy if they demonstrate initial radiographic progression in the absence of significant clinical decline [53]. The iRANO updates recognize that immune therapies may take a longer period of time to confer a clinical benefit and facilitates a mechanism to prevent patients coming off therapy prematurely in the absence of true progressive disease, while ensuring patient safety. Similarly, TTFields require a longer period of treatment (at least 4 weeks of continuous exposure) in order to reach a state of tumor stabilization during the course of therapy [49]. As TTFields exert an antimitotic effect, there will be an initial period where the rate of tumor cell replication will exceed cell killing and clearance rates from the brain. Over time, the rate of cell cytotoxicity and clearance will eventually exceed replication rates and, therefore, there will be a delay until tumor shrinkage is observed on sequential

**Figure 5. Treatment planning in a recurrent glioblastoma patient with nonmeasurable progression post-bevacizumab.**

(A & B) Preprogression axial T1 postcontrast and axial fluid-attenuated inversion recovery (FLAIR) abnormality, with no abnormality at the rostral, superior, lateral ventricle. (C–F) Postprogression axial T1 postcontrast and FLAIR abnormality, and coronal T1 postcontrast and FLAIR images. In this case, planning TTFIELDS treatment using T1 postcontrast sequences will underestimate the extent of tumor progression. (G & H) Treatment planning performed using axial and coronal FLAIR sequences, obtaining tumor coordinates to the margins of FLAIR abnormality.

imaging. In addition, early contrast-enhancing imaging changes may, in fact, represent a local inflammatory response to therapy, not necessarily overt tumor progression [54]. As such, this clinical guideline provides recommendations for maintaining and/or terminating therapy, based on a holistic assessment of the patient's clinical status, concurrent therapies and their imaging findings. Figure 7 describes the algorithm for response assessment and remapping patients receiving TTFIELDS.

As TTFIELDS do not impact the blood–brain barrier, any reduction in tumor size is indicative of a true anti-tumor effect (as opposed to pseudoresponse observed with antiangiogenic therapies). However, as TTFIELDS may be used routinely in the clinical setting in conjunction with other chemotherapies, radiographic response assessment should be evaluated per the RANO criteria. In patients experiencing a complete or partial response, or those with stable disease, it is recommended to maintain TTFIELDS therapy with the same array layout configuration. In instances where there has been

a dramatic reduction in the extent of contrast enhancement (>50% reduction) in the absence of antiangiogenic therapy, it is also feasible for the treating physician to re-map the tumor based on the latest imaging, to ensure that the field is focused to the reduced area of contrast enhancement.

In patients exhibiting radiographic progression from the baseline planning scan, a number of factors should be considered. First, if the patient is a patient with newly diagnosed GB who has recently started TTFIELDS in combination with maintenance TMZ, and has clinically deteriorated, it is recommended to continue TTFIELDS and switch to a second-line chemotherapy as long as the patient remains compliant and able to tolerate the treatment. In the EF-14 Phase III study in patients with newly diagnosed GB, the median duration of TTFIELDS therapy was 9 months, while median PFS was 7.1 months [25], with the majority of patients in the TTFIELDS arm receiving second-line chemotherapies at first progression. If the patient has a recurrent GB and experienced

significant neurologic decline consistent with the imaging changes since initiating TTFields, then treatment should be re-evaluated at the clinician's discretion.

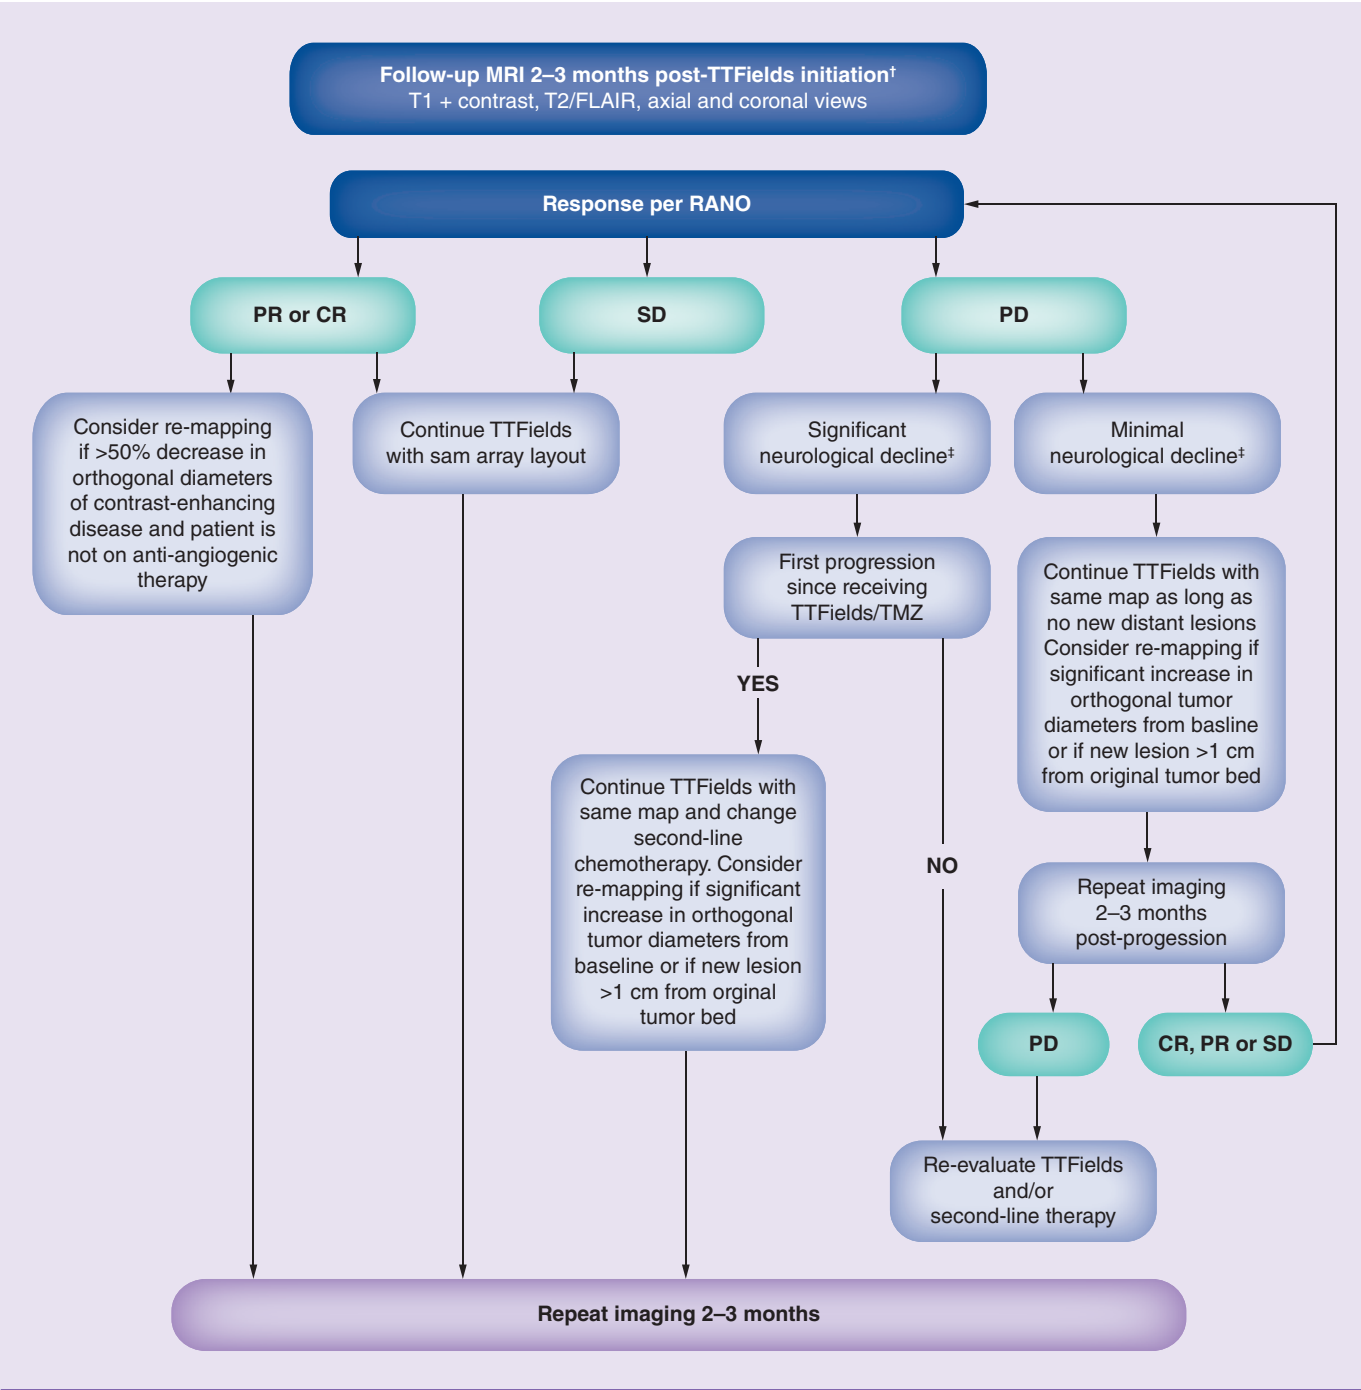

In patients who exhibit radiographic changes consistent with disease progression at the 2-month scan, but who remain neurologically stable and are compliant with therapy, it is feasible to maintain them on TTFields therapy with the same transducer array layout and repeat the scan in another 2–3 months. If however, there

appears to be a significant increase of >25% in size, or new lesions have appeared distal to the original treated tumor bed at the first follow-up scan, then it is recommended to re-plan treatment to include the new or increased size lesions in the field and then continue with therapy. In general, any major changes in imaging from the baseline planning scan should be reviewed in the context of the TTFields treatment field, and re-planning should be considered at the treating physicians' discretion. Since TTFields exert

**Figure 6. Treatment planning for multifocal tumors.** (A & B) Axial views of a multifocal tumor with a multicentric right frontoparietal lesion, and a smaller posterior lesion adjacent to the posterior horn of the lateral ventricle. (C & D) Corresponding coronal views are shown. (B & C) Treatment planning commences with a determination of head size on a slice at the apical level of the orbit and at the level of the ear canal per standard planning. Multifocal lesions are then mapped separately when >1 cm apart. The multicentric anterior lesion is mapped as one contiguous lesion.

**Figure 7. Response assessment and remapping algorithm for tumor treating fields in glioblastoma.**  
†Serves as new reference scan if TTFields treatment continued.  
‡Clinical and neurological decline indicative of tumor progression and not attributable to a co-existing medical condition.

an antimitotic effect exclusive to dividing cells, it may take several months of continuous use before true antitumor responses manifest on sequential imaging.

**Future perspective**  
It has been more than a decade since the anticancer effects of TTFields were first characterized in GB cell lines and clinical studies were initiated.

Today, TTFields are FDA-approved for newly diagnosed and recurrent GB and further development is underway in a variety of solid tumors [55-60]. Since TTFields are a comparatively new anticancer modality compared with surgery, chemotherapy and radiation therapy, this poses additional challenges in the clinic with regard to appropriately training physicians who are certified to plan treatment. This summary guideline proposes a framework for TTFields treatment planning that is consistent with current standards for MRI acquisition and response assessment, which are sensitive to the heterogeneity of tumor activity in imaging and which aim to maximize field intensity at the site of active tumor. Importantly, it proactively addresses early imaging changes that can occur in patients receiving TTFields which may not be indicative of disease progression. The algorithms provide clinicians a roadmap for preventing premature treatment discontinuation of a potentially beneficial modality while balancing safety. As experience with TTFields grows, this guideline will require future revisions to incorporate the integration of advanced imaging modalities in treatment planning, and the potential inclusion of radiologic biomarkers to assess response to treatment. The prospective inclusion of these guidelines in future clinical studies is warranted in order to establish their clinical effectiveness.

# Treatment of Glioma in the 21st Century: An Exciting Decade of Postsurgical Treatment Advances in the Molecular Era

Joon H. Uhm, MD, and Alyx B. Porter, MD

## CME Activity

**Target Audience:** The target audience for *Mayo Clinic Proceedings* is primarily internal medicine physicians and other clinicians who wish to advance their current knowledge of clinical medicine and who wish to stay abreast of advances in medical research.

**Statement of Need:** General internists and primary care physicians must maintain an extensive knowledge base on a wide variety of topics covering all body systems as well as common and uncommon disorders. *Mayo Clinic Proceedings* aims to leverage the expertise of its authors to help physicians understand best practices in diagnosis and management of conditions encountered in the clinical setting.

**Accreditation:** Mayo Clinic College of Medicine and Science is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians.

**Credit Statement:** Mayo Clinic College of Medicine and Science designates this journal-based CME activity for a maximum of 1.0 AMA PRA Category 1 Credit(s).<sup>™</sup> Physicians should claim only the credit commensurate with the extent of their participation in the activity.

**MOC Credit Statement:** Successful completion of this CME activity, which includes participation in the evaluation component, enables the participant to earn up to 1 MOC point in the American Board of Internal Medicine's (ABIM) Maintenance of Certification (MOC) program. Participants will earn MOC points equivalent to the amount of CME credits claimed for the activity. It is the CME activity provider's responsibility to submit participant completion information to ACCME for the purpose of granting ABIM MOC credit.

**Learning Objectives:** On completion of this article, you should be able to (1) identify molecular markers that play a role in the understanding of response to therapy in patients with high-grade glioma; (2) contrast the treatment options available and their efficacy in patients with high-grade glioma and various molecular signatures; and (3) recognize the larger clinical trials that have shaped the current management of high-grade glioma.

**Disclosures:** As a provider accredited by ACCME, Mayo Clinic College of Medicine and Science (Mayo School of Continuous Professional

Development) must ensure balance, independence, objectivity, and scientific rigor in its educational activities. Course Director(s), Planning Committee members, Faculty, and all others who are in a position to control the content of this educational activity are required to disclose all relevant financial relationships with any commercial interest related to the subject matter of the educational activity. Safeguards against commercial bias have been put in place. Faculty also will disclose any off-label and/or investigational use of pharmaceuticals or instruments discussed in their presentation. Disclosure of this information will be published in course materials so that those participants in the activity may formulate their own judgments regarding the presentation.

In their editorial and administrative roles, William L. Lanier, Jr, MD, Terry L. Jopke, Kimberly D. Sankey, and Nicki M. Smith, MPA, have control of the content of this program but have no relevant financial relationship(s) with industry. Dr Uhm has received honoraria from Novocure, manufacturer of the Optune tumor-treating field device that is discussed in this article.

**Method of Participation:** In order to claim credit, participants must complete the following:

1. Read the activity.
2. Complete the online CME Test and Evaluation. Participants must achieve a score of 80% on the CME Test. One retake is allowed.

Visit [www.mayoclinicproceedings.org](http://www.mayoclinicproceedings.org), select CME, and then select CME articles to locate this article online to access the online process. On successful completion of the online test and evaluation, you can instantly download and print your certificate of credit.

**Estimated Time:** The estimated time to complete each article is approximately 1 hour.

**Hardware/Software:** PC or MAC with Internet access.

**Date of Release:** 6/1/2017

**Expiration Date:** 5/31/2019 (Credit can no longer be offered after it has passed the expiration date.)

**Privacy Policy:** <http://www.mayoclinic.org/global/privacy.html>

**Questions?** Contact [dletsupport@mayo.edu](mailto:dletsupport@mayo.edu).

From the Department of Neurology and Division of Neuro-Oncology, Mayo Clinic, Rochester, MN (J.H.U.); and Department of Neurology, Mayo Clinic, Scottsdale, AZ (A.B.P.).

## Abstract

The past decade has brought about major changes in the way we classify and have begun to approach patients with high-grade glioma. As we trend toward personalized medicine, we are now able to utilize the molecular characteristics of each individual's tumor in order to tailor their treatment, particularly if the patient is elderly or has a poor performance status at baseline. We address the state of the practice as of 2016 in regard to chemotherapy, immunotherapy, and tumor-treating fields. The goal of this review is to enhance readers' understanding of the nuances that are allowing clinicians to tailor the treatment of high-grade glioma more specifically.

© 2017 Mayo Foundation for Medical Education and Research ■ Mayo Clin Proc. 2017;92(6):995-1004

The past decade has seen remarkable research advances in glioblastoma that have culminated in tremendous improvements in patient outcome, with extensions in overall survival that have never been

seen previously. Whereas 2-year survival for patients with glioblastoma remained stagnant for decades at a dismal 10%, it nearly tripled to 27% with the advent of temozolomide (TMZ) and increased almost 5-fold for patients

whose tumors harbor a specific genetic alteration (O<sup>6</sup>-methylguanine-DNA methyltransferase gene [MGMT] promoter methylation) in a pivotal study just over 10 years ago.<sup>1-3</sup> The publication of that pivotal study a decade ago was the beginning of one advance after another, each documenting improvements in survival for patients with gliomas. Through advances in the identification of molecular signatures found in these tumors, new directions have been identified that are guiding treatment options in the field. Such new directions include the key role of genetic alterations that will inevitably replace the standard diagnostic procedures based on microscopy (histology/grade). These genetic alterations help to better match specific treatment modalities with a tumor based on its biologic features. This article will highlight several key advances in chemotherapy that have occurred over the past decade that, in turn, direct us toward an even brighter future for our patients.

#### CHEMOTHERAPEUTIC EXTENSION OF SURVIVAL IN PATIENTS WITH GLIOBLASTOMA: TMZ AND THE IDENTIFICATION OF MGMT AS A MOLECULAR MARKER

As the field of neuro-oncology was approaching the end of the 20th century, we had amassed a wealth of information about the molecular biology of glioma cells, which, in turn, identified many potential targets for therapeutics. Figure 1 illustrates the signal transduction pathways that drive glioma growth, with several principal components: the growth factor receptor (GFR) at the cell surface functioning as a “docking station” for growth signals; secondary messenger systems within the cells that are activated by GFRs; the DNA as a common convergence point for many signal transduction pathways to activate expression of cancer-associated genes (oncogenes); and the protein products of those oncogenes that then define the malignant phenotype (cell cycle progression/mitosis, angiogenesis, tumor invasiveness).<sup>1</sup> Each component of this molecular diagram is an ongoing or potential target for therapeutics. Despite numerous drugs developed to inhibit the new molecular targets of signal transduction, in the end it was targeting DNA—the archetypal target in most cancers—that led to the first chemotherapy breakthrough with the advent of TMZ.<sup>2,3</sup>

The benefit of TMZ is summarized in Table 1. For decades, the dogma held that surgery<sup>4</sup> and radiotherapy (RT)<sup>5</sup> were the only 2 therapeutic modalities that improved survival of patients with glioblastoma multiforme (GBM), with only 10% of patients surviving 2 years. A pivotal European/Canadian study by Stupp et al<sup>2</sup> described the addition of a well-tolerated oral chemotherapeutic agent, TMZ, which alkylates DNA (adds methyl group—hence the term *alkylation*—to guanine residue of DNA) (since termed the *Stupp protocol*). The Stupp protocol includes TMZ at 75 mg/m<sup>2</sup> on days 1 through 42 with concomitant RT, followed by TMZ on days 1 through 5 of 28 for 6 consecutive months as adjuvant therapy at a dose of 150 to 200 mg/m<sup>2</sup>. This regimen led to an improvement in 2-year survival to 27%. Furthermore, the presence of a specific alteration—methylation of the MGMT gene promoter—improved 2-year survival to 47%, a 5-fold increase compared with RT alone.<sup>3</sup> The MGMT gene product repairs the DNA modification caused by alkylators such as TMZ, and therefore, silencing of the MGMT gene by promoter methylation is thought to confer increased sensitivity to TMZ. As a result of these 2 back-to-back publications in 2005, RT combined with TMZ became the long-awaited new standard of care in newly diagnosed glioblastoma and MGMT the key molecular marker in our field.

#### TAILORING THE STUPP REGIMEN FOR THE ELDERLY PATIENT POPULATION

MGMT promoter methylation thus became an important prognostic marker in neuro-oncology. Given that the benefit of TMZ is most apparent when this gene alteration is present, MGMT methylation may also be a marker that guides therapy choices. The role of MGMT in helping to guide therapy was highlighted in a series of reports pertaining to optimization of treatment for the elderly population with high-grade glioma.

Table 2 summarizes the evolution of treatment—in particular, the trimming of the Stupp regimen—for the elderly patient population. The French study<sup>6</sup> found that a standard 6-week course of RT (6000 cGy over 6 weeks) improves survival compared with palliative care alone. However, the standard RT course was poorly tolerated by

many patients in the study, leading to a decrease in Karnofsky Performance Status (KPS) score, increased utilization of corticosteroids, and decreased quality of life, raising the question as to whether the standard RT course is suitable for all elderly patients. Particular concern is given to those with poor KPS score because these patients are at greatest risk for poor tolerance of RT and may be unable to complete the full course of therapy. The Canadian study<sup>7</sup> addressed this concern and documented that RT could be abbreviated to 3 weeks without compromising survival and that this regimen was, as anticipated, better tolerated. Nonetheless, the question remained as to whether RT could be omitted altogether and the patient be treated with the well-tolerated oral TMZ alone. In this regard, the subsequent German<sup>8</sup> and Scandinavian<sup>9</sup> studies found that for patients with MGMT methylation, treatment with TMZ alone was not inferior (or perhaps was even superior) to RT. These aforementioned studies evaluated specific RT schedules (without chemotherapy) or TMZ alone but did not evaluate the question of combining RT with chemotherapy. That question was addressed by the European Organisation for Research and Treatment of Cancer (EORTC)/National Cancer Information Center study<sup>10</sup> comparing abbreviated (3 weeks) RT used alone or in combination with TMZ, the latter being a “trimmed down” version of the original Stupp protocol. In a recent report, the study results were positive, with the addition of TMZ to RT improving overall survival, especially in patients with MGMT methylation.

There is no doubt that these recent reports reflect tremendous advances in our treatment options for the elderly patient population. But the results also raise important questions. For one, what age group should be defined as elderly? The patients in the aforementioned studies ranged from 60 years or older to 70 years or older. Also, what matters more—chronological age or biological age? Should all patients over a certain age be barred from a 6-week standard course of RT (which would bar them from many clinical studies)? Despite the questions raised, these recent advances arm the clinician with choices. For example, for the patient whose neurologic/performance status is somewhat compromised, a 3-week

**FIGURE 1.** Signal transduction pathways in glioma. course of RT (with TMZ) is a viable option because it is likely to be better tolerated than 6 weeks of RT. For the patient whose KPS score is quite poor but treatment is still desired, then perhaps TMZ alone could be considered (if the tumor is MGMT methylated). Such diversity of choices was not previously available to this growing patient population in which adverse effects of treatment are all the more apparent than in younger age groups. Undoubtedly, incorporation

TABLE 1. Impact of Temozolomide and MGMT Promoter Methylation on Survival in Patients With Glioblastoma	
Treatment modality	2-Year survival
RT only	10%
RT + TMZ	27%
RT + TMZ + MGMT promoter methylation	47%

MGMT = O<sup>6</sup>-methylguanine-DNA methyltransferase gene; RT = radiotherapy; TMZ = temozolomide.

TABLE 2. Evolution of Treatment Options for Elderly Patients

Study	Question/study/results
Keime-Guibert et al, <sup>6</sup> 2007	<b>Question:</b> Does radiation matter? <b>Study:</b> Randomized study of standard RT (up to 6000 cGy over 6 wk) vs palliative care (patients $\geq 70$ y) <b>Results:</b> Yes. RT improved OS, but there was poor tolerance of 6-wk RT in many patients
Roa et al, <sup>7</sup> 2004	<b>Question:</b> Can RT be abbreviated? <b>Study:</b> 4000 cGy for 3 wk vs 6000 cGy for 6 wk; patients $\geq 60$ y <b>Results:</b> Yes. Abbreviated RT is not inferior to standard 6-wk course; the shortened course of RT was better tolerated as well
Wick et al, <sup>8</sup> 2012	<b>Question:</b> Can RT be omitted and TMZ used alone? <b>Study:</b> 6000 cGy for 6 wk vs TMZ alone; pts $>65$ y <b>Results:</b> Yes. In <i>MGMT</i> methylated patients, TMZ was not inferior (perhaps even superior) to RT
Malmström et al, <sup>9</sup> 2012	<b>Question:</b> How does TMZ alone compare to RT 6 wks vs 3 wks? <b>Study:</b> Comparison of 6 wk of RT vs 3 wk of RT vs TMZ alone <b>Results:</b> Abbreviated RT was not inferior to 6 wk of RT; if tumor is <i>MGMT</i> methylated, using TMZ alone is an option
Perry et al, <sup>10</sup> 2016	<b>Question:</b> Is there any benefit of adding TMZ to the abbreviated RT? <b>Study:</b> 3 wk of RT with or without TMZ; patients $\geq 65$ y <b>Results:</b> Yes. TMZ extends survival when added to 3-wk course of RT; benefits all groups, but benefit is most apparent in <i>MGMT</i> methylated patients
EORTC = European Organisation for Research and Treatment of Cancer; <i>MGMT</i> = O <sup>6</sup> -methylguanine-DNA methyltransferase gene; NCIC = National Cancer Information Center; NOA = Neuro-oncology Working Group; OS = overall survival; RT = radiotherapy; TMZ = temozolomide.	

of other genetic markers (see “A Decade of Advances in Genetics and Chemotherapy: Is Immuno-oncology the Next Frontier?” section) will further advance our understanding and tailoring of therapy for not only elderly patients but patients of all ages.

#### CAN WE FURTHER IMPROVE OUTCOME BY ADDING ANOTHER TREATMENT TO THE RT-TMZ COMBINATION?

Although the demonstration of extended survival with TMZ for patients with GBM was a tremendously welcome and long-awaited advance, we need to continue to build on this foundation. Many of the extracellular and intracellular targets illustrated in Figure 1 have been subjected to drug targeting. To date, no one drug has been found to add another layer of benefit to the RT-TMZ regimen for newly diagnosed GBM.

In the current model for clinical trials for newly diagnosed GBM, promising agents

are first tested in the setting of recurrent glioma (see “When Up-front Therapies Fail: Treatment Options for Recurrent Glioma” section) and if there is evidence of activity (for example, prolongation of progression-free survival), the drug is brought to the frontline setting for evaluation in newly diagnosed patients. In that regard, the monoclonal antibody (bevacizumab) that inhibits angiogenesis by binding and neutralizing a tumor-derived paracrine angiogenic protein (vascular endothelial growth factor [VEGF]) produced impressive results in the recurrent glioma setting.<sup>11,12</sup> However, when tested in conjunction with RT-TMZ in newly diagnosed GBM in 2 large prospective, randomized studies,<sup>13,14</sup> no benefit was seen compared with placebo added to RT-TMZ. Although these results were disappointing, some degree of optimism remains regarding bevacizumab for this patient population. Molecular analysis of patient tumor samples by microarray-based gene expression profile analysis has revealed that patients whose tumor harbors the proneural expression profile live longer when treated with bevacizumab.<sup>15</sup> Such findings underscore the importance of incorporating molecular markers into clinical trials that provide additional layers of data stratified by genetic alterations.

While the search continues for drugs or antibodies to improve outcome for patients with newly diagnosed GBM, exciting results have emerged by way of a medical device. Described as a fourth modality of therapy (the 3 conventional modalities being surgery, RT, and chemotherapy), the tumor-treating field (TTF) device was found in an open-label prospective randomized study to increase survival, boosting the 2-year survival from 29% with RT-TMZ alone to 43% when the TTF device was added in the adjuvant treatment phase in patients with a good performance status.<sup>16</sup> The TTF-based device consists of a battery/power source that is connected to adhesive pads containing arrays that generate a high-frequency alternating electric field. The proposed mechanism of action is that such a device applied to the patient's shaved head interferes with the formation of microtubules required to separate DNA during mitosis. During mitosis, tubulin monomers must undergo polymerization to

form microtubules, but in the presence of the TTF generated by the device, this polymerization is disrupted as the intrinsic electric dipole of each tubulin monomer leads it to align in the direction of the device-generated electric field,<sup>17</sup> leading to disruption of glioma cell mitosis. After its approval by the US Food and Drug Administration (FDA) in late 2015, the TTF device modality is finding its place in our armamentarium of glioma therapeutics.

#### **WHEN UP-FRONT THERAPIES FAIL: TREATMENT OPTIONS FOR RECURRENT GLIOMA**

The aforementioned advances of TMZ added to RT (Stupp regimen), tailoring of RT-TMZ to the elderly population, and abrogation of mitosis by electric fields have changed the landscape of glioma therapy. Nonetheless, for the great majority of patients with GBM, the tumor does ultimately break through frontline therapies. To date, bevacizumab remains the only treatment that has gained widespread acceptance for nonsurgical treatment of recurrent glioma. There are 2 important points about the journey leading to bevacizumab approval for recurrent glioma.

First, innumerable clinical studies evaluating drugs that target GFRs and secondary messenger system components (illustrated in Figure 1) have failed dismally. These failures are due to a myriad of reasons, including poor delivery and redundancy in the signaling system. Delivery of many of these drugs, which are often hydrophilic/polar in nature, is severely impeded by the blood-brain barrier,<sup>18</sup> and hence, effective drug concentrations often cannot be attained.<sup>19,20</sup> Moreover, even if a drug were able to traverse the blood-brain barrier and neutralize its intended GFR target, the tumor cell may not be affected because other GFRs that are also overexpressed continue to drive tumor growth.<sup>21,22</sup>

Second, given the poor experience in targeting specific signaling pathway components in glioma, would better results be attained by targeting an aspect of tumor biology that is not unique to gliomas but shared across most, if not all, tumor types? Such an extrapolation led to the evaluation of angiogenesis inhibitors in patients with brain tumors, and studies before evaluation

in glioma reported exciting results of bevacizumab in many cancer types. Initial studies in glioma<sup>11,23</sup> were generalized from the colorectal carcinoma literature, in which bevacizumab (antibody that neutralizes the principal angiogenic protein, VEGF) was used in combination with irinotecan. These earlier promising reports then led to a randomized study comparing bevacizumab combined with irinotecan vs bevacizumab alone that revealed no significant advantage conferred by irinotecan, hence leading to FDA approval in 2009 of single-agent bevacizumab for treatment of recurrent high-grade glioma.<sup>12</sup>

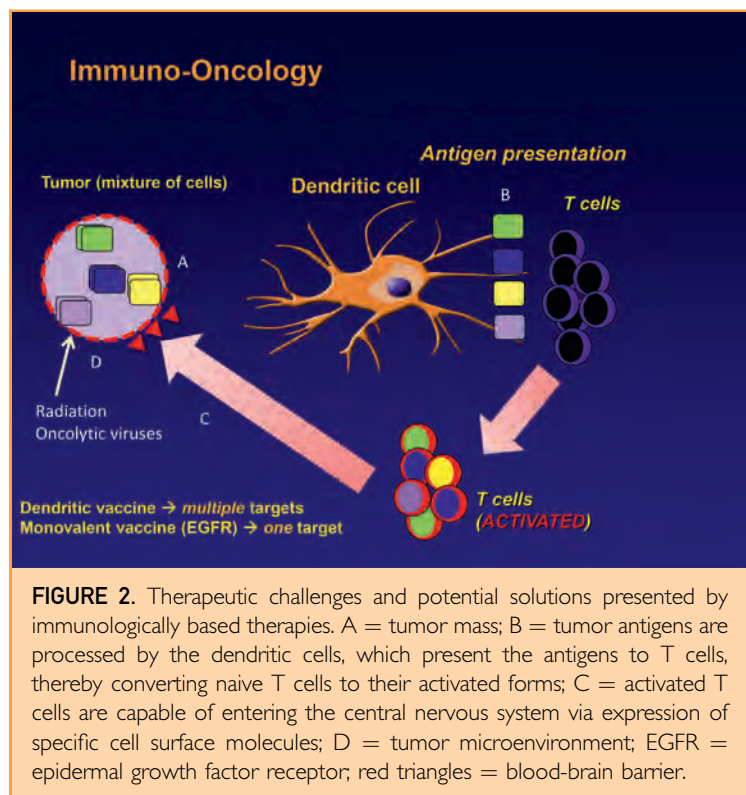

Despite the widespread use of bevacizumab since FDA approval, there still exists no conclusive data that this therapy improves overall survival. In fact, the median time to resistance to bevacizumab is a disappointing 4 months, with tumor cells escaping bevacizumab control due to (1) utilization of alternate angiogenic pathways (eg, platelet-derived growth factor, fibroblast growth factor, mesenchymal stem cells) that are independent of bevacizumab's target VEGF<sup>24</sup> and (2) induction of an evasive phenotype in which tumor cells may take on a more infiltrative/metastatic behavior after exposure to bevacizumab.<sup>25-27</sup>

As a result, many trials have tested other drugs—often the very same small molecule inhibitors that were already known to be ineffective as single agents—and to date, all studies have had negative results. The addition of lomustine, a nitrosourea, to bevacizumab in a phase 2 study increased progression-free and overall survival in the classic subtype of patients with recurrent glioblastoma,<sup>28</sup> and this regimen may show promise in phase 3 studies. Increased understanding of the various angiogenic pathways (especially those not involving VEGF) in glioma growth will then hopefully lead to ways by which we can overcome resistance to current angiogenesis inhibitors.

#### **LEARNING FROM THE PAST: OLDER STUDIES BEARING FRUIT DECADES LATER**

Thus far, we have reviewed promising clinical trial data in high-grade gliomas arising from studies initiated in the early 2000s or later. Similarly, results from studies initiated in the 1990s that have only recently matured have made a huge impact in the care of

patients with low- and intermediate-grade gliomas. Two groups asked the same question: Does chemotherapy add benefit to RT in patients with intermediate- and low-grade glioma? Both studies yielded positive results with a doubling of life expectancy and, moreover, led to further underscoring the importance of molecular markers in treatment planning.

### Intermediate-Grade Glioma

The Radiation Therapy Oncology Group (RTOG) 9402 study, hence named because it was initiated in 1994, evaluated the 3-drug regimen consisting of procarbazine, lomustine [CCNU], and vincristine (PCV) in addition to RT in the treatment of patients with World Health Organization (WHO) grade III/anaplastic oligodendroglial tumors. When initial results were reported in 2006,<sup>29</sup> concurrently with results of a similar study done in Europe by the EORTC,<sup>30</sup> both studies found no difference between the treatment arms. When the data matured 6 years later, the survival curves split specifically for

the patients whose tumors harbored a deletion of chromosome segments 1p and 19q (termed *1p/19q codeletion*). Both studies reported essentially the same findings—the addition of chemotherapy doubled survival from approximately 8 years (RT alone) to 15 years or longer.<sup>31,32</sup> In the absence of *1p/19q codeletion*, the presence of a mutation in the isocitrate dehydrogenase gene (*IDH*) was also predictive of survival benefit from PCV therapy.<sup>33</sup> Both genetic alterations (*1p/19q codeletion* and *IDH* mutations) were not identified until well after these studies had been initiated, but thanks to the foresight of the RTOG and EORTC study teams, archival tumor tissue from study participants could be located and assessed for these key genetic determinants, which yielded practice-altering results guided by molecular variables.

### Low-Grade Glioma

As indicated by its name, the RTOG 9802 study was initiated in 1998. This study, like the one described previously, evaluated the role of adding PCV chemotherapy to RT but this time in the context of low-grade (WHO grade II) gliomas of both oligodendroglial and astrocytic cell types.<sup>34</sup> For patients in the higher-risk category (any patient >40 years of age or any patient regardless of age who had residual tumor after biopsy/surgery), chemotherapy improved overall survival. But similar to the study with grade III oligodendrogliomas, the oligodendroglial tumors as well as tumors harboring the *IDH* mutation derived the most apparent benefit from the chemotherapy. The relatively small number of patients whose tumors were available for *1p/19q* analysis made it difficult to determine if that gene alteration was predictive of chemotherapy benefit.

As such, both the intermediate- and low-grade glioma studies discussed herein determined that the oligodendroglial cell type as well as the presence of *IDH* mutation portends a better outcome with chemotherapy. The experience of these pivotal studies of low- and intermediate-grade glioma is somewhat ironic in that advances in tumor genetics led to a rekindled interest in a chemotherapy regimen (PCV) that was believed to be a thing of the past. Controversy remains regarding

**TABLE 3. Immunotherapeutic Approaches to Address Challenges in Brain Tumor Treatment in Immunological Therapies**

Challenge to treatment	Possible solution/approach
<p>Tumor heterogeneity</p> <p>In “A” on <a href="#">Figure 2</a>, heterogeneity is illustrated by different colored cells (each cell representing a distinct set of molecular alterations and antigens)</p>	<p>Dendritic cell vaccine</p> <p>Antigen-presenting cells or dendritic cells process and present innumerable tumor antigens to T cells to generate activated antitumor T cells</p> <p>Resected tumor serves as a rich source of numerous tumor antigens to be targeted by T cells, thereby addressing the issue of tumor heterogeneity</p>
<p>Antigen presentation by dendritic cells (“B” on <a href="#">Figure 2</a>) is dampened by cell-cell interactions between dendritic cells and T cells. This dampening of antigen presentation serves as a checkpoint to suppress T-cell activation</p>	<p>Checkpoint inhibitor</p> <p>Monoclonal antibodies to disrupt the immunosuppressive cell-cell signaling (example: ipilimumab, a checkpoint inhibitor)</p>
<p>Blood-brain barrier hindering entry of drugs into brain and tumor (“C” on <a href="#">Figure 2</a>)</p>	<p>Activated T cells are capable of entering the central nervous system via expression of specific cell surface molecules</p>
<p>Immunosuppressive factors in tumor microenvironment (“D” on <a href="#">Figure 2</a>)</p> <p>PD-L1 expressed by tumor cells (red triangles on <a href="#">Figure 2</a>) bind to PD-1 receptor on approaching T cells, inducing apoptotic death of T cells</p>	<p>Checkpoint inhibitor</p> <p>Monoclonal antibodies to disrupt interaction between PD-L1 and PD-1 (example: nivolumab)</p>
<p>Immunosuppression by tumor</p> <p>Effectively cloaks tumor cells to avoid detection by T cells and antigen-presenting cells</p>	<p>Dendritic cell vaccine. Patient’s dendritic cells are exposed to tumor antigens extracted from resected tumor to drive T-cell activation</p> <p>Radiotherapy, oncolytic viruses kill a portion of tumor → tumor cell death releases tumor antigens that then drive antigen presentation → recruitment of activated T cells to area of radiotherapy or oncolytic virus injection to augment tumor kill</p>

whether PCV is superior to TMZ in this setting. Perhaps there is no such thing as “old drugs,” but rather simply drugs that have yet to be matched to the appropriate patient population.

#### **A DECADE OF ADVANCES IN GENETICS AND CHEMOTHERAPY: IS IMMUNO-ONCOLOGY THE NEXT FRONTIER?**

The past decade has indeed been eventful, marked by a number of important clinical advances. We can improve survival in low-, intermediate-, and high-grade gliomas by adding chemotherapy to RT, and now for all 3 conditions, the combined therapy is the new standard of care. In all 3 grades of glioma, specific genetic alterations serve as not only prognostic but also predictive markers because they identify which patient population would best benefit from

chemotherapy. However, although the overall life expectancy has increased substantially, treatment resistance is too often an occurrence, largely stemming from 2 major hindrances to therapy—tumor heterogeneity and barriers to drug delivery.

Although a schematic of a single tumor cell as depicted in [Figure 1](#) may be accurate for that one individual tumor cell, the reality is that a patient’s tumor mass is composed of millions of cells, each cell with its potential to diverge and evolve its own molecular alterations, thereby generating extensive intratumoral heterogeneity. In such a system in which, for example, EGFRvIII alteration can be seen in one area of the tumor but not in another, the possible permutations of this and other genetic alterations from one cell to another in a large tumor mass can be endless.<sup>35</sup> Herein lies the challenge of finding a curative treatment—how

**TABLE 4. Molecular/Genetic Markers in Glioma and Their Clinical Relevance—a Road Map for Future Advances in Treatment**

Molecular alteration in glioma	Clinical relevance
<i>MGMT</i> promoter methylation	Sensitivity to alkylator chemotherapy (eg, TMZ)
<i>TERT</i> mutation	Negative prognostic marker when present alone <sup>36,37</sup> ; however, the prognostic/predictive <b>benefit</b> of <i>MGMT</i> methylation may require <i>TERT</i> mutation
1p/19q Codeletion	Positive prognostic marker. Identifies subgroup of gliomas responsive to alkylator-based chemotherapy as well as RT
<i>IDH</i> mutation	Positive prognostic marker. Identifies subgroup of patients with 1p/19q nondeleted oligodendroglioma who may benefit from alkylator chemotherapy
1p/19q Codeletion + <i>IDH</i> mutation + <i>TERT</i> mutation	This combination identifies one of the best prognostic categories for glioma patients
Proneural gene expression profile	Identifies subgroup of patients with GBM who may benefit from bevacizumab added to RT-TMZ
<i>EGFR</i> variant 3 ( <i>EGFRvIII</i> )	Identifies subgroup that may benefit from <i>EGFRvIII</i> -directed vaccine therapies <sup>38</sup>
PD-L1	Activated T cells express PD-1; when PD-L1 (expressed by tumor cells) binds to its receptor PD-1 on T cells, these T cells undergo apoptotic death (hence, mechanism of immune evasion). Target for nivolumab (PD-L1 inhibitor) <sup>39</sup>
CD155	Receptor for infection by oncolytic poliovirus <sup>40</sup>
CD46	Receptor for infection by oncolytic measles virus <sup>41</sup>
Overactive Ras	Permits replication of modified oncolytic reovirus <sup>42</sup>
EGFR = epidermal growth factor receptor; GBM = glioblastoma multiforme; <i>IDH</i> = isocitrate dehydrogenase gene; <i>MGMT</i> = O <sup>6</sup> -methylguanine-DNA methyltransferase gene; RT = radiotherapy; <i>TERT</i> = telomerase reverse transcriptase gene; TMZ = temozolomide.	

to treat such an incredible diversity of tumor cells with just 1, 2, or 3 drugs. The future may lie in immunologic therapies.

Figure 2 and Table 3 illustrate the therapeutic challenges as well as potential solutions presented by immunologically based therapies. The tumor mass (“A” in Figure 2) presents the challenge of the tremendous heterogeneity of cells, each cell harboring antigens distinct from other cells within the mass. These tumor antigens are processed by the dendritic cells, which present the antigens to T cells (“B” in Figure 2), thereby converting naive T cells to their activated forms. There are several checkpoints in this pathway whose function is to dampen T-cell activation in order to avoid an overzealous immune reaction that could lead to autoimmune conditions. Such immunosuppressive checkpoints exist at the point of antigen presentation (interaction between dendritic cell and naive T cells; “B” in Figure 2) and in the tumor microenvironment (“D” in Figure 2) and are

amenable to therapy with checkpoint inhibitors (Table 3).

#### THE MOLECULAR ERA OF NEURO-ONCOLOGY: UPDATED MAP FOR FUTURE ADVANCES

Undoubtedly, the past decade has been a remarkable one, with many advances in treatment options. In regard to chemotherapy, our field has gone from having no clear role for chemotherapy in the treatment of glioma to chemotherapy being able to as much as double life expectancy in the case of low- and intermediate-grade gliomas. Moreover, not only prognosis but also treatment choices can be guided by the tumor’s molecular/genetic alterations as summarized in Table 4.

With the ever-growing importance of genetic alterations to determine prognosis and treatment choices, the diagnostic labels that we ascribe to tumors is shifting from the standard WHO grades II, III, and IV to one of molecularly based diagnoses. This transition

toward molecular classification of gliomas has been evolving over the past 10 to 15 years and reached a tipping point in 2015 when 3 groups (Mayo Clinic/University of California, San Francisco,<sup>36</sup> the Cancer Genome Atlas Network (TCGA) group,<sup>37</sup> and the Japanese group led by Suzuki et al<sup>35</sup>) concurrently published their findings that converged on the same conclusion: that molecularly based diagnosis is superior to diagnosis based on conventional histologic and morphological features of tumor cells. For example, although we would typically expect the prognosis to be grade dependent, exceptions to this general rule are often encountered—eg, a patient with a grade IV/high-grade tumor may have a much longer life expectancy than one who has a grade III/intermediate-grade or even grade II/low-grade tumor. Furthermore, there can be considerable variability in histology-based diagnosis among neuropathologists because of the relatively subjective nature of interpreting cell morphology, nuclear atypia, number of mitotic figures, and other morphological characteristics that determine tumor type and grade. This issue is in contrast to the more binary nature of interpreting genetic tests—for example, 1p/19q alleles are either codeleted or they are not. Along these lines, the aforementioned 3 articles published in 2015 reveal that patients with brain tumors can be grouped into diagnostic clusters based on genetic alterations in which a tumor harboring triple positivity (1p/19q deletion, *IDH* mutation, *TERT* [telomerase reverse transcriptase gene]/telomerase mutation) presents one of the best prognostic groups. Conversely, a tumor harboring none of the alterations portends a prognosis similar to grade IV astrocytoma (glioblastoma) even if the histology may be grade II or III. As such, the 2016 WHO classification of central nervous system tumors has been extensively revised to incorporate genetic alterations.<sup>43</sup> This more accurate classification scheme will also influence future clinical studies, in which eligibility for a specific clinical study will be based more on molecular genetic alterations.

## CONCLUSION

The shift of the neuro-oncology field toward individualized medicine represents a molecular revolution built on a steadfast evolution

and accumulation of many years of rigorous basic and translational research. The past decade that has seen tremendous advances in treatments that prolong life for patients with brain tumors was the product of many preceding years of research. As we look ahead, we rely on the exponential increase in our understanding of glioma biology to serve as fuel for an even better future for our patients. If the numerous scientific advances listed in Table 4 serve in any way as an indicator of what lies ahead, then we can be optimistic.

**Abbreviations and Acronyms:** EORTC = European Organisation for Research and Treatment of Cancer; FDA = Food and Drug Administration; GBM = glioblastoma multiforme; GFR = growth factor receptor; *IDH* = isocitrate dehydrogenase gene; KPS = Karnofsky Performance Status; *MGMT* = O<sup>6</sup>-methylguanine-DNA methyltransferase gene; PCV = procarbazine, lomustine [CCNU], and vincristine; RT = radiotherapy; RTOG = Radiation Therapy Oncology Group; TMZ = temozolomide; TTF = tumor-treating field; VEGF = vascular endothelial growth factor; WHO = World Health Organization

**Potential Competing Interests:** Dr Uhm has received honoraria from Novocure, manufacturer of the Optune tumor-treating field device that is discussed in this article.

**Abstract** We present a 48-year-old male with recurrent glioblastoma (GBM) who was enrolled in the NovoTTF-100A landmark phase III study and has been on device for >6 years. During this time, his magnetic resonance images demonstrated initial growth followed by a slow decrease in enhancement with continued residual disease. Long-term survivors in patients with recurrent GBM are rare, especially in the absence of definitive local treatment such as surgery or radiosurgery. We present the clinical, imaging and pathological findings for this patient in relation to use of the NovoTTF-100A device.

**Keywords** Glioblastoma · Brain tumor · Tumor treatment fields · Recurrent tumor · Survival

### Introduction

Patients with recurrent glioblastoma (GBM) have poor outcomes with median survival of <6 months in most series [1]. Reports of patients having prolonged survival with GBM are limited mainly to treatments for primary disease [2–5]. With patients living longer, more investigations are being conducted in second line treatment [1]. The recent phase II (BRAIN) study demonstrated median survival of 9 months with bevacizumab-based treatment [1].

NovoTTF-100A is a recently FDA-approved device that creates electrical fields within the tumor that disrupt cell division during anaphase [6]. Patients wear non-invasive transducer arrays on their scalp during most of the day. A landmark phase III trial in recurrent GBM demonstrated the device has equivalent therapeutic benefit to chemotherapy, with less toxicity and with improved quality of life measures [6].

We report a patient enrolled in this trial that has continued to respond to the NovoTTF-100A device for more than 6 years, representing one of the longest reported survivors of recurrent GBM.

### Case report

A 48-year-old Hispanic male presented in February 2004 with a generalized tonic-clonic seizure. MRI of the brain demonstrated an enhancing mass in the right parietal lobe. He initially underwent debulking of the mass, and final

pathology was interpreted as suggestive of infiltrating glioma. Postoperatively, he developed noticeable, 4/5, left hemiparesis with left facial droop. Without a conclusive diagnosis, he was recommended a repeat craniotomy, which he declined (Figs. 1, 2).

Nine months later, based on imaging studies he underwent a second right frontoparietal craniotomy and biopsy with debulking of the mass. He received impregnated carmustine wafers during surgery. Pathological analysis demonstrated GBM having brisk mitotic activity, widespread microvascular proliferation, pseudopalisading necrosis with significant nuclear pleomorphism and atypia. It also had oligodendroglial features, and chromosomal analysis revealed heterozygous deletions of both 1p and 19q chromosomes [7]. Methylation analysis for the promoter region of the *MGMT* gene demonstrated positive methylation.

He was treated with the involved-field cranial irradiation and concomitant daily temozolomide, which he tolerated well. Although he had a delay in starting the maintenance portion, imaging studies following his eleventh cycle demonstrated progression of his enhancing lesion. Almost 2 years after his initial tumor resection, he underwent a

third craniotomy for surgical debulking, which demonstrated similar pathology as his second surgery. Five months later, he received radiation boost via Gamma Knife as he showed increased enhancement. Imaging performed 4 months after this procedure revealed progression. He was then enrolled in the Novocure phase III recurrent trial, and on November 15, 2006, he began treatment with the NovoTTF-100A device for 22 h daily. Since starting this treatment, he has been clinically stable. During the initial MRI scans on study, his enhancing lesion grew in size, but did not meet criteria for disease progression, and therefore, he remained in the trial. This was then followed by a period of slow but continued decrease in enhancement that has since stabilized. He remains active and functional and continues using the device.

## Discussion

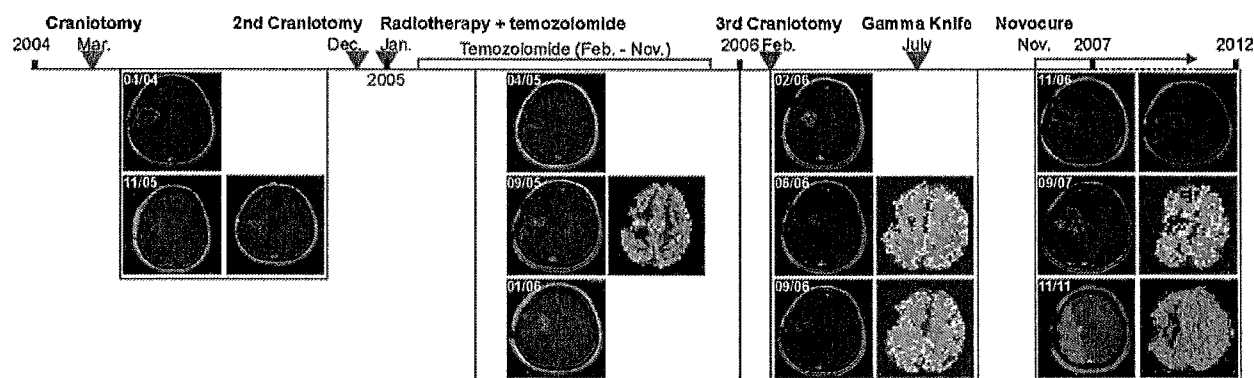

The NovoTTF-100A device is a portable battery-operated device that generates alternating electric fields called tumor treating fields (TTFields). Charged intracellular dipoles such as microtubules are required for cell division and are

**Fig. 1** **a** Hematoxylin and eosin-stained section of brain biopsy specimen from 4/2004 with mildly increased cellularity and glial atypia suggestive of infiltrating glioma (magnification:  $\times 200$ ). **b** Hematoxylin and eosin-stained section of GBM from 11/2004 with increased cellularity, significant glial atypia and pleomorphism, mitotic activity and microvascular proliferation (magnification:  $\times 400$ ). **c** Hematoxylin and eosin-stained section of GBM from

11/2004. Some tumor areas were dominated by tumor cells featuring round nuclei consistent with an oligodendroglioma component (magnification:  $\times 400$ ). **d** Hematoxylin and eosin-stained section of resection specimen from 2/2006 with highly cellular glioma and vascular changes consistent with radiation-related changes (magnification:  $\times 400$ )

**Fig. 2** Results of diagnostic MRI throughout disease course. T1-weighted MRI of the brain with Gadolinium contrast-axial section with accompanied perfusion study at similar structural level. These images corresponds to the timeline-demonstrating therapy and disease activity. In the perfusion study, voxels that are red correspond to high

blood flow, as seen with the outer cerebral vasculature and growing tumor. Blue colored voxels correspond to areas of low blood flow, as seen in white matter, with gradation of blood flow visualized by changes in the red-to-blue color spectrum. Note that most recent image does not demonstrate increased perfusion

disrupted by TTFields. This disruption leads to an arrest on cell proliferation with subsequent apoptosis and theoretically provides cytotoxic therapy [6]. The prolonged survival in our patient receiving only TTFields is consistent with these pre-clinical findings.

Our patient's diagnosis of GBM was confirmed by having two independent neuro-pathologic reviews. Histologically, the hallmarks of GBM were present: widespread microvascular proliferation and pseudopalisading necrosis. However, he does have the subclass of GBM-containing oligodendroglial component [7]. Although debated, this is associated with improved outcomes. Our patient's clinical course was progressive, requiring multiple craniotomies, chemotherapy and radiation.

Radiation necrosis also needs be considered. Radiation damage to vascular endothelial cells can result in compromise of the blood-brain barrier. Although radiation necrosis cannot be ruled out, the enhancing lesion on MRI demonstrated increased cerebral blood volume on perfusion studies, which is consistent with recurrent tumor. Also, the resected samples in the two craniotomies following his initial treatment retained active tumor cells. It is notable that patients with methylated *MGMT* gene have increased risk of developing pseudoprogression; however, he started TTF therapy nearly 2 years from receiving his concurrent radiation and temozolomide. Finally, radiation necrosis or pseudoprogression will in time generally have a self-limiting course, although many cases will have disease progression as viable tumor frequently coexists within areas of radiation necrosis, and our patient has been on device for greater than 6 years with imaging evidence of residual enhancement [8]. This leads us to conclude that the imaging findings represent disease progression.

In conclusion, our patient is a unique long-term survivor of GBM with evidence of residual disease. He has received

significant amount of treatment, but currently for >6 years is only receiving the NovoTTF-100A device.

# Dexamethasone exerts profound immunologic interference on treatment efficacy for recurrent glioblastoma

E T Wong<sup>\*,1</sup>, E Lok<sup>1</sup>, S Gautam<sup>2</sup> and K D Swanson<sup>\*,1</sup>

<sup>1</sup>Brain Tumor Center and Neuro-Oncology Unit, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA 02215, USA and <sup>2</sup>Division of Biostatistics, Department of Medicine, Beth Israel Deaconess Medical Center, Boston, MA 02215, USA

**Background:** Patients with recurrent glioblastoma have a poor outcome. Data from the phase III registration trial comparing tumour-treating alternating electric fields (TTFields) vs chemotherapy provided a unique opportunity to study dexamethasone effects on patient outcome unencumbered by the confounding immune and myeloablative side effects of chemotherapy.

**Methods:** Using an unsupervised binary partitioning algorithm, we segregated both cohorts of the trial based on the dexamethasone dose that yielded the greatest statistical difference in overall survival (OS). The results were validated in a separate cohort treated in a single institution with TTFields and their T lymphocytes were correlated with OS.

**Results:** Patients who used dexamethasone doses  $>4.1$  mg per day had a significant reduction in OS when compared with those who used  $\leq 4.1$  mg per day, 4.8 vs 11.0 months respectively ( $\chi^2 = 34.6$ ,  $P < 0.0001$ ) in the TTField-treated cohort and 6.0 vs 8.9 months respectively ( $\chi^2 = 10.0$ ,  $P < 0.0015$ ) in the chemotherapy-treated cohort. In a single institution validation cohort treated with TTFields, the median OS of patients who used dexamethasone  $>4.1$  mg per day was 3.2 months compared with those who used  $\leq 4.1$  mg per day was 8.7 months ( $\chi^2 = 11.1$ ,  $P = 0.0009$ ). There was a significant correlation between OS and T-lymphocyte counts.

**Conclusions:** Dexamethasone exerted profound effects on both TTFields and chemotherapy efficacy resulting in lower patient OS. Therefore, global immunosuppression by dexamethasone likely interferes with immune functions that are necessary for the treatment of glioblastoma.

Patients with recurrent glioblastoma have limited treatment options. Bevacizumab is a standard of care for patients with recurrent glioblastoma and it produces an objective response rate of 25–60% (Wong *et al*, 2011). However, its ability to prolong patient overall survival (OS) is questionable (Iwamoto and Fine, 2010; Reardon *et al*, 2012). The NovoTTF-100A device is another FDA-approved treatment for recurrent glioblastoma that works by emitting tumour-treating alternating electric fields (TTFields) via two pairs of transducer arrays placed orthogonally on the scalp and acts to perturb tumour cells during mitosis (Kirson *et al*, 2004, 2007; Gera *et al*, 2015). Preclinical data show that cells affected by TTFields exhibit violent plasma membrane blebbing that disrupts the normal spatial ordering of the mitotic chromosomes.

This results in asymmetric chromosome segregation and aneuploidy owing to defects in cytokinesis and aberrant mitotic exit. Furthermore, these cells also exhibit signs of stress that include elevated cell surface expression of calreticulin, which makes them more readily detectable by phagocytic immune cells, facilitating an immune response against the tumour (Lee *et al*, 2013). Importantly, the NovoTTF-100A device was demonstrated to possess equivalent efficacy when compared with best physician's choice (BPC) chemotherapy in the registration phase III clinical trial, but without the myeloablative toxicities associated with systemic chemotherapies that may cause secondary systemic infection or interference with immune effector function (Vecht *et al*, 1994; Hughes *et al*, 2005; Stupp *et al*, 2012; Fonkem and Wong, 2012).

More recently, a prespecified interim analysis of the results from an upfront phase III clinical trial in newly diagnosed glioblastoma patients, comparing NovoTTF-100A plus adjuvant temozolomide *vs* adjuvant temozolomide alone, revealed significantly improved patient outcome with a respective progression-free survival of 7.1 *vs* 4.0 months and OS of 19.6 *vs* 16.6 months (Stupp *et al*, 2014). Compared with newly diagnosed glioblastomas, patients with recurrent glioblastoma likely have several factors that led to a worse outcome, including clonal evolution of the tumour, evasion of the immune system and reduction of immune competence because of prior exposure to chemotherapy.

Dexamethasone is commonly used to treat neurologic symptoms caused by the glioblastoma (Vecht *et al*, 1994). However, it also has a plethora of systemic toxicities, including gastrointestinal haemorrhage with or without perforation, infection, and hyperglycaemia (Heimdal *et al*, 1992). Although dexamethasone has not been shown to interfere directly with the efficacy of treatments against glioblastoma, there is emerging evidence from both preclinical and clinical data in other malignancies to suggest that dexamethasone may affect the patient's antitumour immunity. First, although the immune system has evolved multiple mechanisms to recognise and eliminate neoplastic cells (Senovilla *et al*, 2013), tumours emerge within the patient when they escape immune surveillance (Mittal *et al*, 2014). At this point, the tumour further subverts the immune system by eliciting normal wound healing and tissue remodelling responses, whereas promoting a state of immune privilege within the tumour microenvironment (Schreiber *et al*, 2011). In this setting, dexamethasone may potentiate existing local immunosuppression via global induction of  $\text{I}\kappa\text{B}\alpha$  and inhibition of NF- $\kappa\text{B}$  activity in lymphocytes, resulting in global immunosuppression (Auphan *et al*, 1995). Second, dexamethasone can lower the number of  $\text{CD4}^+$  lymphocytes in newly diagnosed patients with glioblastoma treated with radiation alone or in combination with temozolomide, and this attenuated  $\text{CD4}^+$  lymphocyte count is associated with increased infections and decreased survival (Hughes *et al*, 2005; Grossman *et al*, 2011). Lastly, recent clinical trial data have shown that there were more systemic and central nervous system responders to ipilimumab, an immune checkpoint inhibitor, in the cohort taking no dexamethasone as compared with the cohort taking dexamethasone, suggesting that dexamethasone interferes with the efficacy of ipilimumab (Margolin *et al*, 2012).

In this paper, we present evidence that immune suppression by dexamethasone markedly interferes with the clinical efficacy of two disparate therapies for recurrent glioblastoma: electric field-based therapy delivered by the NovoTTF-100A as well as conventional chemotherapies. Unlike prior clinical trials, the cohort treated with TTField monotherapy offered us an opportunity to study unambiguously the effect of dexamethasone on patient survival unencumbered by concurrent chemotherapies that suppress the immune system. We also present data that strongly support a role for immune competence in effecting TTField treatment by analysing T-cell subsets measured in a separate cohort of patients for validation.

## PATIENTS AND METHODS

**Patients.** Subjects signed informed consent from their respective treating institutions before participation in the phase III trial comparing NovoTTF-100A *vs* BPC chemotherapy (Fonkem and Wong, 2012; Stupp *et al*, 2012). A *post hoc* analysis of the dexamethasone effect on the two cohorts was performed based on anonymised data obtained from the sponsor, from whom the corresponding author had full access to the primary data. The outcome of the analysis was then validated retrospectively, under

an institutional review board-approved protocol from Dana Farber/Harvard Cancer Center (protocol no. 12-519), using a separate cohort of patients who were treated with NovoTTF-100A and bevacizumab at Beth Israel Deaconess Medical Center.

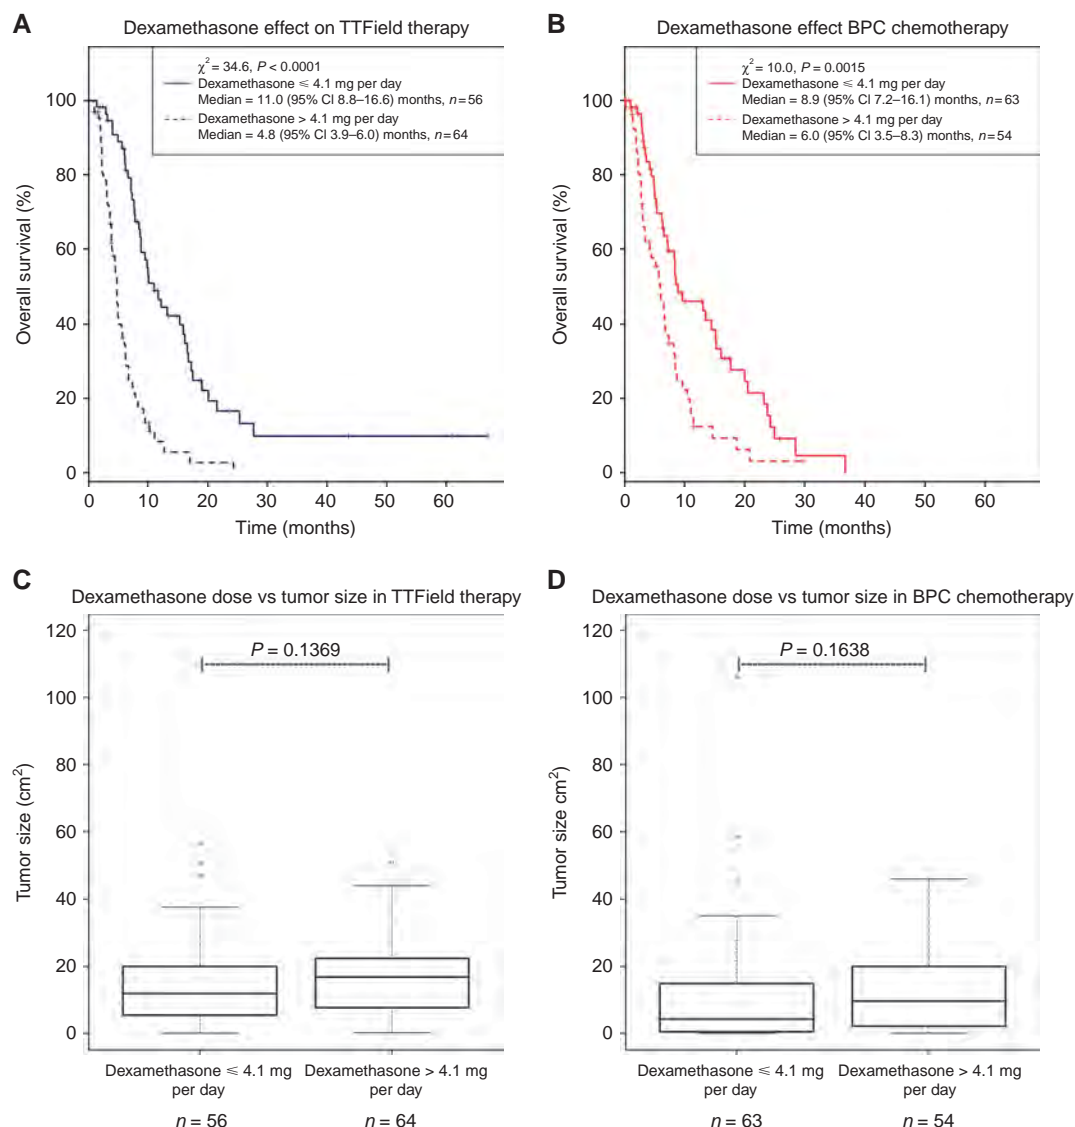

**Statistical analysis.** Statistical analyses were performed by using R statistics base package (<http://www.r-project.org>) and its libraries. Two-tailed Wilcoxon's rank-sum test with continuity correction was used to determine whether two independent groups of data were statistically different from each other. A modified binary search algorithm (Knuth, 1971; Tøndel *et al*, 2002), written in R, was used to iteratively partition data in both two and three dimensions. The Loess local nonparametric polynomial regression was used to perform curve fitting of the OS as a function of dexamethasone dose (Cleveland, 1979; Shipley and Hunt, 1996; Cleveland and Loader, 1996) and OS was analyzed using Kaplan–Meier statistics (Kaplan and Meier, 1958).

## RESULTS

**Effect of dexamethasone on TTField therapy and BPC chemotherapy.** Our previous *post hoc* analysis of responders in the phase III trial demonstrated that responders to TTField therapy required significantly lower doses of dexamethasone compared with non-responders (Wong *et al*, 2014). We therefore investigated further whether there was a threshold dose of dexamethasone that affected outcome within the entire trial population. Using an unsupervised binary partitioning algorithm (Knuth, 1971; Tøndel *et al*, 2002), we stratified the TTField therapy cohort based on the dexamethasone dose that yielded the greatest statistical difference in median OS. The results revealed that subjects who used  $>4.1$  mg per day dexamethasone ( $n=64$ ) exhibited a significantly shortened median OS of 4.8 months (95% confidence interval (CI): 3.9–6.0) *vs* those who used  $\leq 4.1$  mg per day ( $n=56$ ), with a median OS of 11.0 months (95% CI: 8.8–16.6) ( $\chi^2=34.6$ ,  $P<0.0001$ ; Figure 1A). We then used the same dexamethasone cutoff to stratify control patients in the BPC chemotherapy cohort and observed a similar, albeit less robust, dichotomisation, with a respective median OS of 6.0 months (95% CI: 3.5–8.3) ( $n=54$ ) *vs* 8.9 months (95% CI: 7.2–16.1) ( $n=63$ ) ( $\chi^2=10.0$ ,  $P=0.0015$ ; Figure 1B) for those receiving  $>4.1$  *vs*  $\leq 4.1$  mg per day of dexamethasone, respectively. There are two potential explanations for these results: either patients with larger, more aggressive tumours required a higher dose of dexamethasone for symptom control or doses of dexamethasone  $>4.1$  mg per day interfered with both therapeutic interventions used in this trial. However, tumour size did not differ statistically between patient cohorts that used dexamethasone at either  $>4.1$  or  $\leq 4.1$  mg per day (Figures 1C and D). Therefore, factors other than tumour size influence the OS of subjects receiving high *vs* low doses of dexamethasone.

To further investigate the effect of dexamethasone on patient outcome, we compared the survival characteristics of the cohort treated with TTField therapy to the one treated with BPC chemotherapy in the respective dexamethasone dosage groups. First, we compared the two treatment groups when the dosage of dexamethasone used was  $\leq 4.1$  mg per day. Although the two OS curves overlapped ( $\chi^2=0.9$ ,  $P=0.3510$ ; Figure 2A), we detected a marked separation between these two curves at time points less than the median OS. Indeed, when we compared the survival curves of the two cohorts for subjects who used dexamethasone  $\leq 4.1$  mg per day and possessed survival times of less than the median OS, we found a significant difference between the two subgroups, with a median OS of 6.6 (range 1.4–10.1) months for the TTField-treated subgroup ( $n=31$ ) *vs* 3.9 (range 0.0–8.6) months for the BPC chemotherapy-treated subgroup ( $n=40$ ) ( $P=0.0015$ ; Figure 2C). However, for subjects who lived longer

**Figure 1.** Kaplan–Meier OS and tumour size with respect to dexamethasone requirement of  $\leq 4.1$  vs  $> 4.1$  mg per day from subjects enrolled in the phase III trial comparing TTField therapy vs BPC chemotherapy. **(A)** Subjects enrolled in the TTField treatment arm taking dexamethasone  $\leq 4.1$  (solid blue) vs  $> 4.1$  (dashed blue) mg per day, which was determined by an unsupervised binary partitioning algorithm. Subjects who used  $\leq 4.1$  mg per day of dexamethasone ( $n = 56$ ) had a median OS of 11.0 months (95% CI: 8.8–16.6) as compared with those who used  $> 4.1$  mg per day ( $n = 64$ ) had a median OS of 4.8 months (95% CI: 3.9–6.0) ( $\chi^2 = 34.6, P < 0.0001$ ). **(B)** Subjects enrolled in the BPC chemotherapy arm taking dexamethasone  $\leq 4.1$  (solid red) vs  $> 4.1$  (dashed red) mg per day was determined by the same unsupervised binary partitioning algorithm. Subjects who used  $\leq 4.1$  mg per day of dexamethasone ( $n = 63$ ) had a median OS of 8.9 months (95% CI: 7.2–16.1) as compared with those who used  $> 4.1$  mg per day ( $n = 54$ ) had a median OS of 6.0 months (95% CI: 3.5–8.3) ( $\chi^2 = 10.0, P = 0.0015$ ). **(C)** Box-and-whisker plot of bidimensional tumour size in the TTField therapy cohort that received dexamethasone  $\leq 4.1$  vs  $> 4.1$  mg per day. Subjects who took dexamethasone  $\leq 4.1$  mg per day ( $n = 56$ ) had a median tumour size of 11.9 (range 0.0–56.7)  $\text{cm}^2$  as compared with those who used  $> 4.1$  mg per day ( $n = 64$ ) had a median tumour size of 16.8 (range 0.3–51.0)  $\text{cm}^2$  ( $P = 0.1369$ ). **(D)** Box-and-whisker plot of bidimensional tumour size in the BPC chemotherapy cohort that received dexamethasone  $\leq 4.1$  vs  $> 4.1$  mg per day. Subjects who took dexamethasone  $\leq 4.1$  mg per day ( $n = 63$ ) had a median tumour size of 4.2 (range 0.0–11.2)  $\text{cm}^2$  as compared with those who used  $> 4.1$  mg per day ( $n = 54$ ) had a median tumour size of 9.6 (range 0.0–46.0)  $\text{cm}^2$  ( $P = 0.1638$ ).

than the median OS, there was no difference in the OS curves, with a median OS of 16.7 (range 11.0–66.9) months for the TTField-treated subgroup ( $n = 25$ ) vs 16.8 (range 8.9–36.7) months for the BPC chemotherapy-treated subgroup ( $n = 23$ ) ( $P = 0.5773$ ; Figure 2E). In contrast, among subjects who received high dexamethasone doses of  $> 4.1$  mg per day, the overlapping OS curves ( $\chi^2 = 1.5, P = 0.2240$ ; Figure 2B) appeared to diverge for the subjects whose survival were greater than the median OS. Remarkably, the TTField-treated subgroup was worse compared with the BPC chemotherapy-treated subgroup when treated with

dexamethasone doses  $> 4.1$  mg per day, with a respective median OS of 6.7 (range 4.8–24.3) months ( $n = 29$ ) vs 8.7 (range 6.0–29.6) months ( $n = 22$ ) ( $P = 0.0097$ ; Figure 2D). However, for subjects whose survival were less than the median OS and used  $> 4.1$  mg per day dexamethasone, there was no difference between the TTField-treated and the BPC chemotherapy-treated subgroups, with the former having a median OS of 3.0 (range 0.8–4.5) months ( $n = 35$ ) as compared with the latter having a median OS of 2.8 (range 0.2–5.8) months ( $n = 32$ ) ( $P = 0.8456$ ; Figure 2E). Collectively, the data in Figures 2C and D indicate that the extent

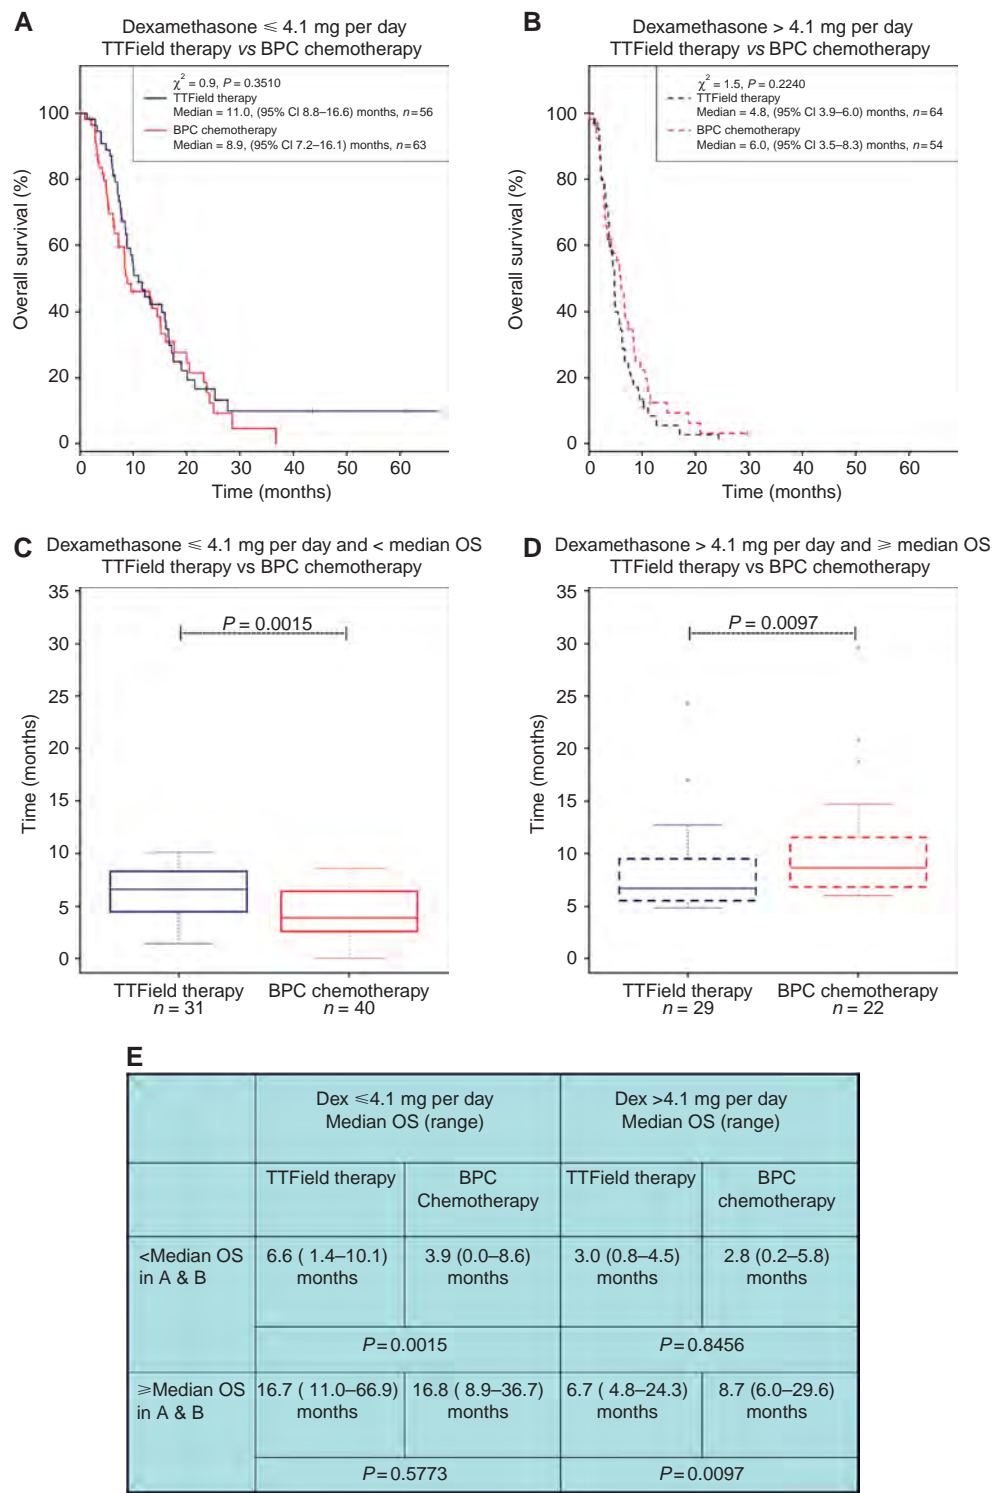

Figure 2. Comparison of OS in subjects treated with TTField therapy vs BPC chemotherapy segregated by dexamethasone usage. (A) Comparison of subjects using dexamethasone  $\leq 4.1$  mg per day in both TTField therapy (blue) and BPC chemotherapy (red) arms. (B) Comparison of subjects using dexamethasone  $> 4.1$  mg per day in both TTField therapy and BPC chemotherapy arms. (C) Box-and-whisker plot of OS between TTField vs BPC chemotherapy-treated subjects using  $\leq 4.1$  mg per day of dexamethasone and  $<$  the median OS in (A). The median OS was 6.6 months (range 1.4–10.1) for TTField-treated subjects ( $n = 31$ ) vs 3.9 months (range 0.0–8.6) for BPC chemotherapy-treated subjects ( $n = 40$ ) ( $P = 0.0015$ ). (D) Box-and-whisker plot of OS between TTFields vs BPC chemotherapy-treated subjects using  $> 4.1$  mg per day of dexamethasone and  $\geq$  the median OS in (B). The median OS was 6.7 months (range 4.8–24.3) for TTField-treated subjects ( $n = 29$ ) vs 8.7 months (range 6.0–29.6) for BPC chemotherapy-treated subjects ( $n = 22$ ) ( $P = 0.0097$ ). (E) Median OS, range, and  $P$ -values for the four subgroups: (i) dexamethasone  $\leq 4.1$  mg per day and  $<$  median OS in (A), (ii) dexamethasone  $> 4.1$  mg per day and  $<$  median OS in (B), (iii) dexamethasone  $\leq 4.1$  mg per day and  $\geq$  median OS in (A), and (iv) dexamethasone  $> 4.1$  mg per day and  $\geq$  median OS in (B).

of dexamethasone exposure not only predicted treatment efficacy but also strongly suggest that TTField therapy is superior to BPC chemotherapy in the setting of low dexamethasone usage. However, under the influence of higher dexamethasone usage, the benefit of TTField therapy appeared to be negated to a greater extent when compared with BPC chemotherapy as if TTField-treated subjects were not provided with any therapy at all.

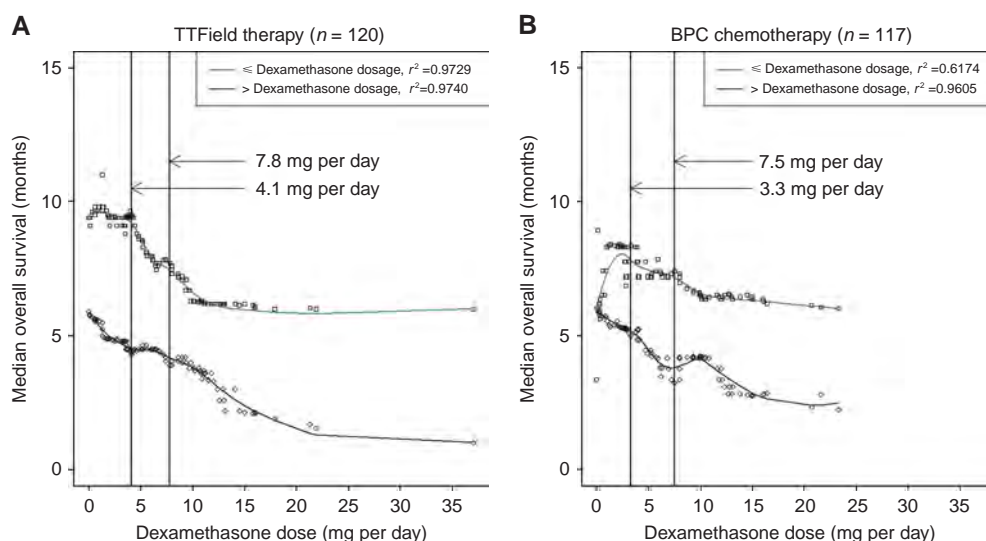

#### Dose-dependent effect of dexamethasone on treatment efficacy.

We next asked whether or not dexamethasone has a dose-dependent influence on treatment efficacy by analysing the entire dose spectrum used in the trial. We partitioned the TTField-treated cohort using a dexamethasone dose cutoff from 0.0 to 37.0 mg per day, plotted the respective median OS of the groups at  $\leq$  cutoff or  $>$  cutoff vs successive dexamethasone dosages, and fitted the data with the best curves using the nonparametric Loess local polynomial regression (Figure 3) (Cleveland, 1979; Cleveland and Loader, 1996; Shipley and Hunt, 1996). In addition, we plotted the log-rank  $P$ -values of the dichotomised groups in each successive dexamethasone dosage and found two nadir  $P$ -values of 0.00000008 and 0.00002524 corresponding to dexamethasone doses of 4.1 and 7.8 mg per day, respectively. We observed that there was decremental OS starting at a dexamethasone dose of 4.1 mg per day and, with successive increases of dexamethasone, reached an inflection point at 7.8 mg per day, after which the rate of OS decreased slowly (Figure 3A).

We also performed the same dose-dependent analysis of dexamethasone in the BPC chemotherapy-treated cohort and found a nadir  $P$ -value of 0.00163291 at 3.3 mg per day and another of 0.00011858 at 7.5 mg per day. Similarly, the best-fit curve derived in Figure 3B also suggests that the dexamethasone dose near 4 mg per day may also represent a point at which decremental OS can be observed with successive increases in dexamethasone dosage. This progressive decrement in OS occurred with successive increases of dexamethasone until an inflection point is observed at a dose near 7.5 mg per day, after which the rate of OS decreased slowly. Taken together, both cohorts experienced interference from dexamethasone at a dose near 4.0 mg per day and a maximal effect was observed near 7.5 mg per day.

**Validation of the dexamethasone effect on TTField-treated patients from a single institution.** We next proceeded to validate the observed dexamethasone effect on patient outcome within the trial by retrospectively analysing our own single-institution cohort. From November 2012 to February 2014, we treated 38 patients (Table 1) using TTField monotherapy as treatment or in combination with bevacizumab, whereas dexamethasone usage was aggressively reduced. Three patients who were referred specifically to our institution did not receive TTField therapy because of patient choice of other treatments, severe medical comorbidities, or advanced intracranial disease that was deemed more suitable for hospice care. Among the remaining 35 patients, their median OS was 4.3 months (95% CI: 3.5–8.7). To properly compare this cohort with the subjects enrolled in the phase III trial, we included only those with a KPS  $\geq$  70 or greater ( $n = 23$ ) in our validation set. This sub-population exhibited a median OS of 8.0 months (95% CI: 3.8–13.8) compared with 3.2 months (95% CI: 1.4–NA) for the remaining patients with a KPS  $<$  70 ( $n = 12$ ) ( $\chi^2 = 8.5$ ,  $P = 0.0035$ ; Figure 4A). We then applied a cutoff of dexamethasone 4.1 mg per day as was found in our previous binary partitioning analysis. Patients who used dexamethasone  $\leq$  4.1 mg per day had a significantly longer OS compared with those who used  $>$  4.1 mg per day, with a median OS of 8.7 months (95% CI: 6.7–NA) ( $n = 19$ ) vs 3.2 months (95% CI: 1.2–NA) ( $n = 4$ ), respectively ( $\chi^2 = 11.1$ ,  $P = 0.0009$ ; Figure 4B). Although our single-institution cohort has fewer patients compared with the cohorts in the phase III trial, we nevertheless observed a robust segregation of OS in the patient groups, validating the previously observed effect of dexamethasone on patient outcome.

Comparison of patients within the validation cohort with a KPS  $\geq$  70 and dexamethasone usage  $\leq$  4.1 mg per day ( $n = 19$ ) to the phase III TTField therapy cohort who used dexamethasone  $\leq$  4.1 mg per day ( $n = 56$ , from Figure 2A) revealed no statistical difference between the two groups, with a median OS of 8.7 months (95% CI: 6.7–NA) vs 11.0 months (95% CI: 8.8–16.6), respectively ( $\chi^2 = 2.1$ ,  $P = 0.1520$ ; Figure 4C). We next asked whether important prognostic factors within our cohort varied relative to patients within the phase III cohort by examining the possible effects of age and tumour size. The median age of our

**Figure 3.** Loess local polynomial regression of median OS vs dexamethasone dose. Dexamethasone was treated as a discrete variable successively and the median OS was plotted for the group  $\leq$  (green) and  $>$  (blue) compared with the variable dosage of dexamethasone. Curve fitting was performed using the Loess local polynomial regression. **(A)** In the TTField therapy cohort ( $n = 120$ ), there was decremental OS from 4.1 mg per day that reached an inflection point at 7.8 mg per day, after which the rate of OS decrease slowed. **(B)** In the BPC chemotherapy cohort ( $n = 117$ ), there was decremental OS from 3.3 mg per day that reached an inflection point at 7.5 mg per day, after which the rate of OS decrease slowed.

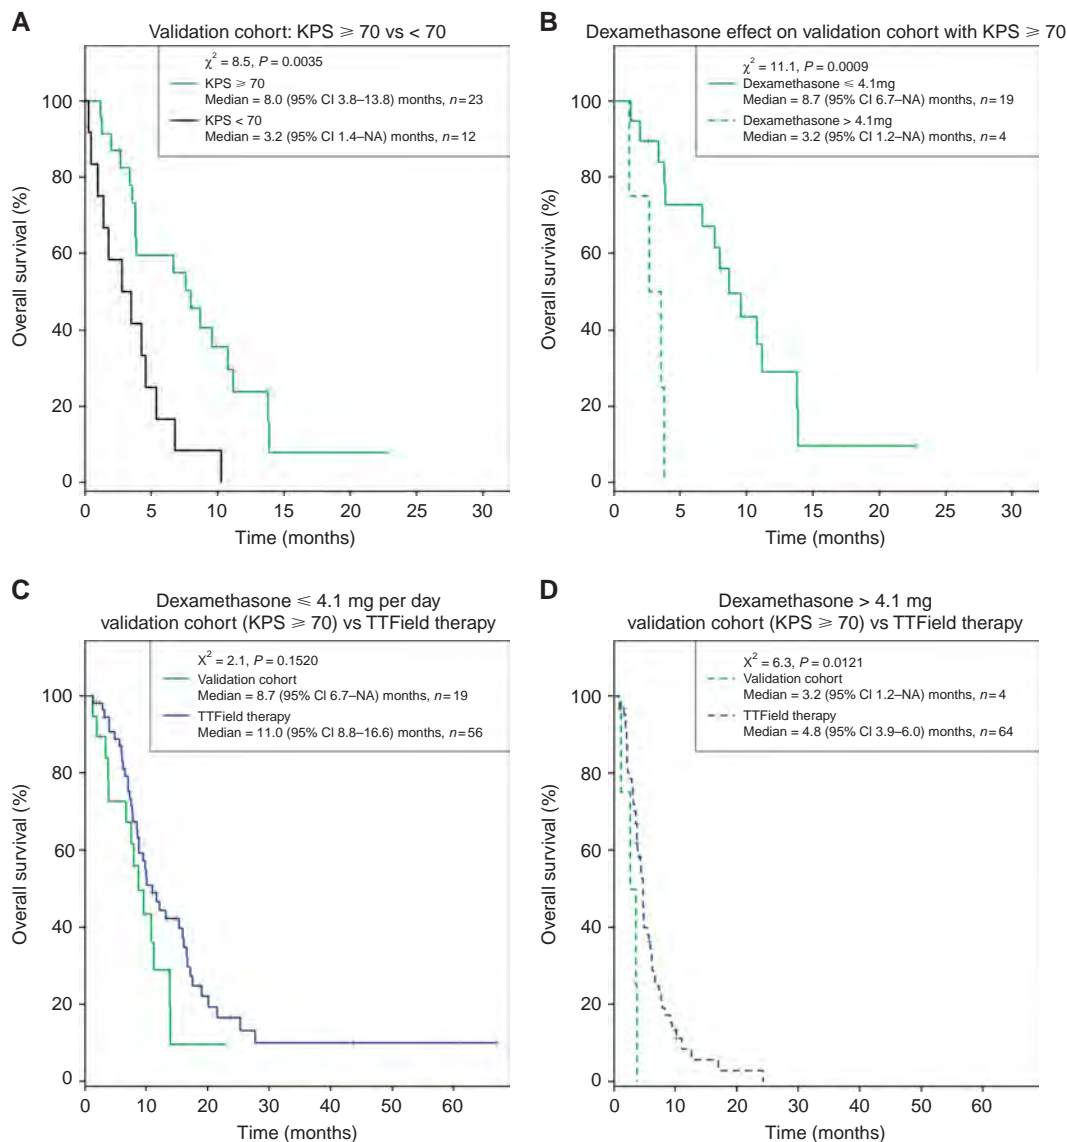

Table 1. Patient characteristics in the validation cohort and the NovoTTF-100A cohort in phase III trial			
Patient characteristics	Validation cohort (n = 35)	NovoTTF-100A cohort (n = 120)	P-value
Age (range)	57 (30 – 77) years	54 (24–80) years	
Gender			
Male	22 (63%)	92 (77%)	
Female	13 (37%)	28 (23%)	
Karnofsky performance status			
Median	70 (range 50–90)	80 (range 50–100)	
Tumour size, bidimensional			
T1 Gad, median (range) (cm <sup>2</sup> )	12.2 (0.3 – 40.6)	14.2 (0.0–56.7)	0.6178
FLAIR, median (range) (cm <sup>2</sup> )	35.2 (7.0 – 90.9)	N/A	
Dexamethasone dose			
Median (range) (mg per day)	3.0 (0.0 – 15.0)	4.7 (0.0–37.5)	
Absolute T-cell subsets			
CD3, median (range) (cells per mm <sup>3</sup> )	733 (70 – 1458)	N/A	
CD4, median (range) (cells per mm <sup>3</sup> )	414 (25 – 788)	N/A	
CD8, median (range) (cells per mm <sup>3</sup> )	302 (44 – 1039)	N/A	
Prior therapy			
First recurrence	6 (17%)	11 (9%)	
Second recurrence	10 (29%)	58 (48%)	
Third recurrence	19 (54%)	51 (43%)	
Prior bevacizumab	25 (71%)	23 (19%)	
Outcome			
Overall survival, median (months)	4.3 (95% CI: 3.5–8.7)	7.1 (95% CI: 6.1–8.8)	0.0468
Abbreviations: CI = confidence interval; FLAIR = fluid-attenuated inversion recovery; Gad = gadolinium; N/A = not applicable; TTF = tumour-treating alternating electric field.			

cohort was 57 (range 30–77) years and it is not different from the median age of 54 (range 24–80) years in the TTField-treated cohort from the phase III trial (Stupp *et al*, 2012). Average tumour size in our cohort as measured by gadolinium-enhanced T1-weighted MRI showed a median bidimensional measurement of 12.2 (range 0.30–40.6) cm<sup>2</sup>, which is similar to the median bidimensional measurement of 14.2 (0.0–56.7) cm<sup>2</sup> in the TTField-treated phase III cohort (*P* = 0.6178; Table 1). However, 15 of 23 patients (65%) were already on bevacizumab before their neuroimaging studies, possibly interfering with tumour measurement because bevacizumab can reduce vascular permeability in tumours causing decreased gadolinium enhancement (Wong and Brem, 2008). Further, blockade of vascular endothelial growth factor can promote an invasive and diffuse glioblastoma phenotype that result in tumours possessing greater size than can be measured on gadolinium-enhanced T1-weighted MRI (Norden *et al*, 2008; Lu *et al*, 2012). We therefore measured the bidimensional size of the FLAIR abnormality. Indeed, in our cohort, the median bidimensional FLAIR abnormality was 29.6 (range 7.0–60.2) cm<sup>2</sup>, which is more than two times the tumour size observed on gadolinium-enhanced T1-weighted MRI in the phase III trial (Stupp *et al*, 2012). As expected, this bevacizumab effect on tumour measurement was corroborated in our entire patient cohort (*n* = 38) by the strong correlation between the size of the gadolinium-enhanced T1-weighted and FLAIR measured bidimensional tumour size among those not on bevacizumab (*r*<sup>2</sup> = 0.7333, *n* = 10; Supplementary Figure 1A), whereas no such correlation was seen among those on bevacizumab (*r*<sup>2</sup> = 0.1446, *n* = 27; Supplementary Figure 1B). Furthermore, we found that patients in our validation cohort who used dexamethasone > 4.1 mg per day (*n* = 4) had a worse outcome compared with the corresponding cohort in the phase III trial (*n* = 64), with a median OS of 3.2 months (95% CI: 1.2–NA) vs 4.8 months (95% CI: 3.9–6.0), respectively ( $\chi^2$  = 6.3, *P* = 0.0121; Figure 4D). Therefore, our single-institution validation cohort, who had KPS ≥ 70, used dexamethasone ≤ 4.1 mg per day and possessed greater tumour burden, compared favourably with those treated with TTFields therapy in the phase III trial, but those with KPS ≥ 70 but used

dexamethasone > 4.1 mg per day probably suffered from a worse outcome compared with the corresponding trial cohort.

**Patient immune characteristics and TTField therapy efficacy.** Dexamethasone has been associated with profound immunosuppression (Hughes *et al*, 2005; Grossman *et al*, 2011) and it may severely limit a patient’s ability to mount an antitumour immune response against the glioblastoma (Zitvogel *et al*, 2008a). Our data clearly demonstrated that dexamethasone doses higher than a threshold level of 4.1 mg per day correlated with a poorer patient outcome during TTField therapy. This finding strongly suggests an immunological component behind the efficacy of this intervention and that factors required for general immune competence may have a role in predicting therapeutic outcome in our patients. We therefore analysed their CD3<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> T-lymphocyte subsets during the course of their treatment. Using the unsupervised binary partitioning approach described above for dexamethasone dose, we attempted to identify whether there was any threshold for the absolute CD3<sup>+</sup>, CD4<sup>+</sup>, or CD8<sup>+</sup> T-lymphocyte count, which yielded the greatest statistical difference in OS when used to stratify our patient population. Significantly, this analysis revealed that the median OS of patients with absolute CD3<sup>+</sup> ≤ 382 cells per mm<sup>3</sup> was 2.0 months (95% CI: 1.2–NA) (*n* = 7). In contrast, the median OS of those with CD3<sup>+</sup> > 382 cells per mm<sup>3</sup> was 7.6 months (95% CI: 4.3–13.9) (*n* = 22) ( $\chi^2$  = 17.8, *P* < 0.0001; Figure 5A), with the data showing that patient survival was positively correlated with the absolute numbers of CD3<sup>+</sup> T lymphocytes. Similarly, we found that patients with absolute CD4<sup>+</sup> ≤ 236 cells per mm<sup>3</sup> exhibited a median OS of 2.7 months (95% CI: 1.4–NA) (*n* = 9) as compared with those with CD4<sup>+</sup> > 236 cells per mm<sup>3</sup> with a median OS of 8.0 months (95% CI: 4.6–NA) (*n* = 20) ( $\chi^2$  = 13.4, *P* = 0.0002; Figure 5B). Furthermore, patients with an absolute CD8<sup>+</sup> count of ≤ 144 cells per mm<sup>3</sup> exhibited a median OS of 2.0 months (95% CI: 2.0–NA) (*n* = 5) as compared with 6.8 months (95% CI: 3.9–13.8) (*n* = 24) for those with CD8<sup>+</sup> > 144 cells per mm<sup>3</sup> ( $\chi^2$  = 8.1, *P* = 0.0045; Figure 5C). We next asked whether CD3<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> lymphocyte counts was related to the overall status of the patient’s peripheral

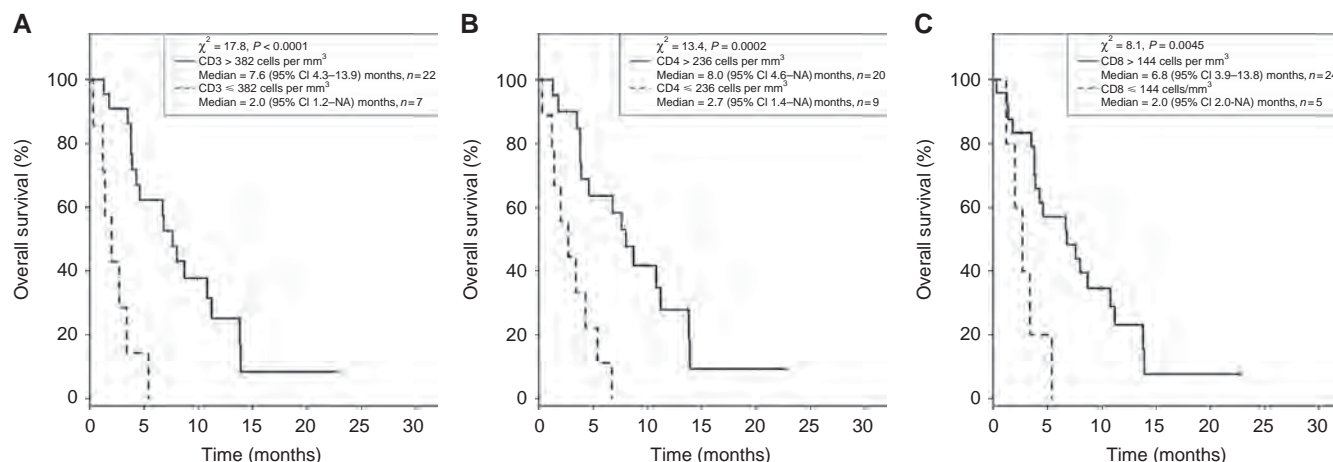

**Figure 4.** Kaplan–Meier estimates of survival in the validation cohort from a single institution. **(A)** The Kaplan–Meier survival curves for patients with KPS  $\geq 70$  (solid green) vs those with KPS  $< 70$  (solid black). **(B)** Dexamethasone effect on the cohort with KPS  $\geq 70$  by comparing patients taking dexamethasone  $\leq 4.1$  (solid green) vs those taking  $> 4.1$  mg per day (dashed green). **(C)** Comparison of the TTField-treated subjects who used  $\leq 4.1$  mg per day of dexamethasone in the phase III trial (from Figure 2A) vs the validation cohort with having KPS  $\geq 70$  and taking dexamethasone  $\leq 4.1$  mg per day. **(D)** Comparison of the TTField-treated subjects who used  $> 4.1$  mg per day of dexamethasone in the phase III trial (from Figure 2B) vs the validation cohort with having KPS  $\geq 70$  and taking dexamethasone  $> 4.1$  mg per day.

blood counts and dexamethasone requirement. As expected, there was a correlation between  $CD3^+$  and  $CD4^+$  cells ( $r^2 = 0.6949$ ) and between  $CD3^+$  and  $CD8^+$  cells ( $r^2 = 0.5001$ ) but not between  $CD4^+$  and  $CD8^+$  cells ( $r^2 = 0.0733$ ). However, there was no correlation between white blood cells (WBC) and  $CD3^+$  cells ( $r^2 = 0.0053$ ), WBC and  $CD4^+$  cells ( $r^2 = 0.0023$ ), and WBC and  $CD8^+$  cells ( $r^2 = 0.0032$ ). No correlation was also detected between platelets and  $CD3^+$  cells ( $r^2 = 0.2576$ ), platelets and  $CD4^+$  ( $r^2 = 0.2746$ ), and platelets and  $CD8^+$  ( $r^2 = 0.0887$ ). Similarly, there was no correlation between the daily dexamethasone dose and  $CD3^+$  cells ( $r^2 = 0.1888$ ), dexamethasone and  $CD4^+$  cells ( $r^2 = 0.1531$ ), and dexamethasone and  $CD8^+$  cells ( $r^2 = 0.0451$ ). Taken together,  $CD3^+$ ,  $CD4^+$ , and  $CD8^+$  lymphocyte counts appear to be independent of the peripheral blood counts and dexamethasone dose effect. Therefore, T-lymphocyte counts may serve as an independent measure of immunocompetence in our patients and predict treatment outcome when using NovoTTF-100A.

## DISCUSSION

Our previous *post hoc* analysis of responders in the phase III trial comparing NovoTTF-100A monotherapy and BPC chemotherapy for recurrent glioblastoma revealed that dexamethasone and prior low-grade glioma histology were predictors of response (Wong *et al*, 2014). Traditionally, oncologists view dexamethasone's influence on glioblastoma patients from the perspective of its antioedema effect from the tumour (Vecht *et al*, 1994), antiemetic efficacy against emetogenic chemotherapies, infections from its systemic immunosuppressive property (Vecht *et al*, 1994; Hughes *et al*, 2005), and changes in contrast enhancement on computed tomography (Chamberlain *et al*, 1988) or MRI (Ostergaard *et al*, 1999). Because dexamethasone has the potential to produce profound toxicities in patients in large part by suppressing their immune system and it is a clinically modifiable factor, we therefore extended our analysis of possible dexamethasone effect on outcome

**Figure 5.** Wilcoxon's rank-sum test of the optimal cutoff T-lymphocyte subsets as determined by an unsupervised binary partitioning algorithm. **(A)** Median OS of patients with absolute CD3<sup>+</sup> ≤ 382 vs > 382 cells per mm<sup>3</sup> was 2.0 months (range 0.3–5.4) (n = 7) and 7.7 months (range 1.3–22.7) (n = 25), respectively (P = 0.0017). **(B)** Median OS of patients with absolute CD4<sup>+</sup> ≤ 236 vs > 236 cells per mm<sup>3</sup> was 2.7 months (range 0.3–6.7) (n = 9) and 8.0 months (range 1.3–22.7) (n = 23), respectively (P = 0.0029). **(C)** Median OS of patients with absolute CD8<sup>+</sup> ≤ 144 vs > 144 cells per mm<sup>3</sup> was 2.7 months (range 1.2–5.4) (n = 5) and 7.6 months (range 0.3–22.7) (n = 27), respectively (P = 0.0313).

to the entire trial cohort. In this study, we have uncovered compelling evidence that dexamethasone counteracted the therapeutic efficacy of TTFields. Further, we also found that its use negatively correlated with survival in the cohort treated with chemotherapy. Our analysis is the first to show this significant impact of dexamethasone on treatment efficacy and patient OS, which is a discrete and unequivocal endpoint in contrast to progression-free survival or response for the conduct of clinical trials for recurrent glioblastomas.

In contrast to commonly used chemotherapeutic regimens, TTField monotherapy does not exert deleterious effects on the immune system, and thus, unlike the chemotherapy-treated cohort, TTField-treated subjects did not receive concurrent immunosuppressive agents other than dexamethasone during the entire trial period. Therefore, this trial provided us with a unique opportunity to examine the interference of dexamethasone on the clinical outcome of patients without the confounding influence of cytotoxic chemotherapies. Given our previous observation that responders from this trial had low dexamethasone usage (Wong *et al*, 2014), we first asked whether we could determine a threshold of dexamethasone exposure below which a benefit in patient survival could be detected within the entire cohort. Using an unsupervised mathematical algorithm, we found that a dexamethasone dose of 4.1 mg per day produced the greatest statistical segregation of OS in the TTField-treated cohort, and subjects who received > 4.1 mg per day had a 2.3-fold decrease in median OS compared with those who used ≤ 4.1 mg per day. Notably, using this dose level to stratify the control cohort treated with BPC chemotherapy also produced a statistically significant, but less robust, OS segregation, and subjects who received > 4.1 mg per day had a 1.5-fold decrease in median OS compared with those who used ≤ 4.1 mg per day. Within both cohorts, patients exhibited a decrease in OS starting at about 4.0 mg per day, with progressive decrement until a dosage of 8.0 mg per day, above which there was no further decrease in OS. Therefore, our data indicate that dexamethasone has a generalised and profound interference on treatment efficacy regardless of whether the treatment has non-cytotoxic or cytotoxic properties on the haematopoietic system.

Our analysis strongly indicates that dexamethasone interferes with the efficacy of both TTFields and BPC chemotherapies, the latter of which consisted largely of alkylating chemotherapies. In the sub-populations taking ≤ 4.1 mg per day of dexamethasone, 31 subjects treated with TTField monotherapy exhibited a better

outcome compared with the corresponding 40 subjects treated with BPC chemotherapy. This small but statistically significant benefit occurred within the first 11 months, after which the OS of the two cohorts overlapped and the benefit from TTField therapy dissipated. In contrast, for the sub-population taking > 4.1 mg per day of dexamethasone, 29 subjects treated with TTField monotherapy exhibited a worse outcome relative to the corresponding 22 subjects treated with BPC chemotherapy. Therefore, high dexamethasone dosage appears to negate or counteract the effect of both TTField therapy and BPC chemotherapy. Because the overall trial population in the TTField-treated cohort is only 120, the benefit of treatment in the 31 (26%) subjects taking ≤ 4.1 mg per day of dexamethasone is essentially negated by the hindrance caused by the 29 (24%) patients taking > 4.1 mg per day of dexamethasone when the populations were not segregated based on dexamethasone burden. This dexamethasone interference with TTField efficacy may explained the improved outcome seen in the trial for newly diagnosed glioblastoma patients (Stupp *et al*, 2014), who were not as severely affected by treatment effects when compared with recurrent glioblastoma patients who had a longer exposure to cytotoxic chemotherapy, dexamethasone, or both.

Our data also indicate that T-lymphocyte subsets may have an important role in the outcome of our validation cohort of patients treated with TTField therapy, with prolonged OS associated with absolute CD3<sup>+</sup> > 382 cells per mm<sup>3</sup>, CD4<sup>+</sup> > 235 cells per mm<sup>3</sup>, and CD8<sup>+</sup> > 144 cells per mm<sup>3</sup> in an unsupervised analysis. Hughes *et al* (2005) and Grossman *et al* (2011) both showed that dexamethasone induces a drop in CD4<sup>+</sup> lymphocyte count, which predisposes glioblastoma patients to infectious complications, and a CD4<sup>+</sup> count < 200 cells per mm<sup>3</sup> is associated with poor survival. However, we also noted that dexamethasone's immunosuppressive effect also blunted the therapeutic efficacy of TTField therapy and chemotherapy, probably as a result of its global interference with the patient's immune system. This notion is supported by our *in vitro* experiments, which demonstrated that cells attempting to divide in the presence of the TTFields are disrupted in mitosis during the metaphase-to-anaphase transition and experienced aberrant mitotic exit (Gera *et al*, 2015). These cells subsequently exhibited changes consistent with immunogenic cell death and thus were susceptible to immune elimination (Lee *et al*, 2011, 2013). Because subjects that received dexamethasone ≤ 4.1 mg per day in the phase III trial exhibited benefit from TTField therapy, the observed benefit is strongly consistent with an

increased immunogenicity of cells affected by TTFields. Furthermore, a number of cytotoxic chemotherapy agents, such as doxorubicin, 5-fluorouracil, and oxaliplatin, can induce either genomic or cytoplasmic stress in the tumour cell leading to immunogenic cell death (Zitvogel *et al*, 2008b). Although the extent of immunostimulatory effects of alkylators, such as lomustine, carmustine, procarbazine, and temozolomide is unknown, dacarbazine has been shown to upregulate NKG2D ligands on tumour cells and thereby target them for immune elimination by natural killer (NK) cells and CD8<sup>+</sup> cytotoxic T-lymphocytes (Hervieu *et al*, 2013). Furthermore, alkylating agents have been shown to induce the secretion of ATP and HMGB1, both of which are danger signals that can activate immune responses against dying cells (Zong *et al*, 2004). Lastly, in myeloma patients, dexamethasone can severely block lenalidomide-induced NK cell activation (Hsu *et al*, 2011). Taken together, there is a strong indication from our data that the cytotoxic agents used in the trial against recurrent glioblastomas also act by inducing immune responses against the tumour and that concurrent dexamethasone usage negated this benefit.

There are a number of limitations in the interpretation of our findings. First, our data only allowed us to examine global immunosuppression in our patients but provide no means to assess local immunosuppression within the tumour microenvironment. This local suppression of immune surveillance is thought to be mediated by arginase, regulatory T cells, and myeloid-derived immunosuppressive cells (Fecci *et al*, 2006; Jacobs *et al*, 2010; Raychaudhuri *et al*, 2011). Nevertheless, removal of global immunosuppressive factors is the first step towards successful antiglioblastoma therapy. Second, our T-lymphocyte analysis only measured cells in the adaptive immune system. However, TTField therapy and certain chemotherapy agents could potentially induce an NK cell response against the glioblastoma (Hervieu *et al*, 2013; Lee *et al*, 2013). However, the observed dexamethasone effect on absolute CD3<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> lymphocytes could also negatively influence the activation of other cytotoxic subsets such as NK cells (Hsu *et al*, 2011). Therefore, future analysis of the specific effects of dexamethasone on glioblastoma treatment would need to include the global effect on these cells.

In conclusion, dexamethasone exerted a profound interference on the therapeutic effects of both TTField therapy and BPC chemotherapies. The threshold dose at which dexamethasone was able to be used with minimal interference on these treatments was 4.1 mg per day or lower. In our validation set of TTField-treated patients, the cluster that had the longest OS had CD3<sup>+</sup> > 382 cells per mm<sup>3</sup>, CD4<sup>+</sup> > 236 cells per mm<sup>3</sup>, and CD8<sup>+</sup> > 144 cells per mm<sup>3</sup>. Taken together, these data strongly suggest that the stimulation of immunity against the tumour operates in both of these therapeutic approaches. Future clinical trials for recurrent glioblastoma, as well as other types of brain tumours, may need to take into account the influence of dexamethasone on therapeutic outcome.

## Abstract

The NovoTTF-100A device emits frequency-tuned alternating electric fields that interfere with tumor cell mitosis. In phase III trial for recurrent glioblastomas, NovoTTF-100A was shown to have equivalent efficacy and less toxicity when compared to Best Physician's Choice (BPC) chemotherapy. We analyzed the characteristics of responders and nonresponders in both cohorts to determine the characteristics of response and potential predictive factors. Tumor response and progression were determined by Macdonald criteria. Time to response, response duration, progression-free survival (PFS)  $\pm$  Simon–Makuch correction, overall survival (OS), prognostic factors, and relative hazard rates were compared between responders and nonresponders. Median response duration was 7.3 versus 5.6 months for NovoTTF-100A and BPC chemotherapy, respectively ( $P = 0.0009$ ). Five of 14 NovoTTF-100A responders but none of seven BPC responders had prior low-grade histology. Mean cumulative dexamethasone dose was 35.9 mg for responders versus 485.6 mg for nonresponders in the NovoTTF-100A cohort ( $P < 0.0001$ ). Hazard analysis showed delayed tumor progression in responders compared to nonresponders. Simon–Makuch-adjusted PFS was longer in responders than in nonresponders treated with NovoTTF-100A ( $P = 0.0007$ ) or BPC chemotherapy ( $P = 0.0222$ ). Median OS was longer for responders than nonresponders treated with NovoTTF-100A ( $P < 0.0001$ ) and BPC chemotherapy ( $P = 0.0235$ ). Pearson analysis showed strong correlation between response and OS in NovoTTF-100A ( $P = 0.0002$ ) but not in BPC cohort ( $P = 0.2900$ ). Our results indicate that the response characteristics favor NovoTTF-100A and data on prior low-grade histology and dexamethasone suggest potential genetic and epigenetic determinants of NovoTTF-100A response.

## Introduction

Patients with recurrent glioblastoma have poor prognosis. Objective response rates to alkylating chemotherapy are low, ranging 5–8% [1, 2]. Although bevacizumab has a remarkably high response rate of 25–60% [3], its ability to prolong the overall survival (OS) of patients in the recurrence setting is marginal and it still awaits testing in a randomized clinical trial [4, 5]. Those who failed

bevacizumab are unlikely to respond to subsequent therapy [6, 7]. Therefore, new and innovative therapies are needed for recurrent glioblastoma.

The NovoTTF-100A device is a novel cancer treatment that delivers low-intensity, intermediate frequency (200 kHz) tumor treating electric fields (TTFields) via transducer arrays applied onto the scalp. TTFields disrupt glioblastoma cells during mitosis, resulting in apoptosis, aneuploidy, asymmetric chromosome segregation, and

defects in centrioles and mitotic spindles [8–10]. In a phase III trial for recurrent glioblastoma, this device has been shown to have equivalent efficacy when compared to conventional chemotherapies, including bevacizumab [11]. Notably, the NovoTTF-100A cohort had more responders than the Best Physician's Choice (BPC) chemotherapy cohort [11, 12] and NovoTTF-100A responders may offer insights into the mechanisms of action of TTFields on glioblastoma. Therefore, we undertake this post hoc analysis on the characteristics between responders in the NovoTTF-100A and BPC cohorts, as well as differences between responders and nonresponders within each cohort.

## Patients and Methods

### Patients

The conduct and the overall results of the pivotal phase III trial were previously published [11] and outlined in the CONSORT diagram (Fig. 1). Tumor response and progression were determined according to Macdonald criteria [13] and confirmed by independent radiology review.

### Statistical analysis

The corresponding author has full access to the data and is responsible for the outcome of analysis. Kaplan–Meier distributions [14] were generated using the R statistical package ([www.r-project.org](http://www.r-project.org)). The median, 95% confidence interval (95% CI), and *P* values were computed for time to response and response duration for responders in both NovoTTF-100A and BPC chemotherapy cohorts. Prognostic factors were compared between groups using Wilcoxon rank-sum test.

To examine whether NovoTTF-100A had a greater or weaker efficacy over BPC chemotherapy, we computed the relative density of hazard rates for responders and nonresponders to determine an increasing or decreasing rate of tumor progression [15, 16]. Plots of hazard rate density as a function of time to tumor progression were generated using R.

OS and progression-free survival (PFS) between responders and nonresponders were analyzed using Kaplan–Meier statistics [14]. Additional PFS analysis was done to minimize potential bias in the responder population by introducing the Simon–Makuch correction [17, 18]. This was done by adding the median time to response to both responders' response duration and nonresponders' time to progression, followed by derivation of Kaplan–Meier distributions. The median PFS and 95% CI were computed in the adjusted groups and independence was tested by chi-squared statistics.

The distribution of OS was also compared to time to response and response duration. Linear regression was fitted to determine a one-to-one relationship between the two time intervals and the  $r^2$  value was computed. Pearson rank coefficient was computed to determine the strengths of the correlation. A scatter plot of the two time intervals was generated in R and independence was tested by chi-squared statistics.

## Results

### Responder characteristics

The NovoTTF-100A cohort ( $N = 120$ ) had more responders than the BPC cohort ( $N = 117$ ) (Table 1). The respective median time to response was 8.4 (95% CI 6.9–9.9) months in the NovoTTF-100A responders and 5.8 (95% CI 3.6–8.0) months in the BPC chemotherapy

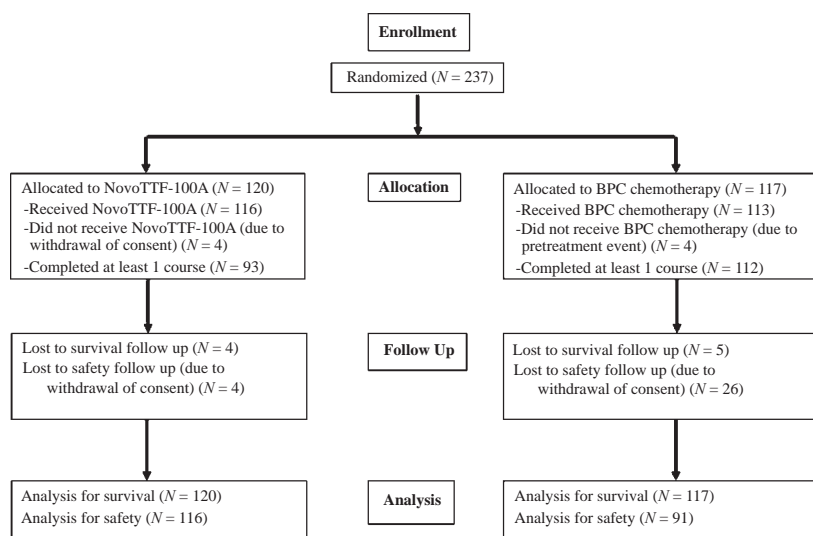

Figure 1. CONSORT diagram.

responders ( $P = 0.5755$ , Figs. 2 and 3). Six of 14 responders (43%) had initial growth of the tumor at 2–24 months while on NovoTTF-100A suggesting a period of tumor pseudoprogression. The median response duration was 7.3 (95% CI 0.0–16.6) and 5.6 (95% CI 3.8–7.5) months, respectively ( $P = 0.0009$ ). These data indicate that, compared to BPC chemotherapy responders, the NovoTTF-100A responders may have had a longer time to response after treatment initiation and, when responded, they had a more durable response.

**Table 1.** Clinical and response characteristics of NovoTTF-100A versus BPC chemotherapy cohorts.

<b>Median (95% CI) OS</b>		
Responders	24.8 (17.5–N/A) months	20.0 (14.5–N/A) months
Nonresponders	6.2 (5.0–7.7) months	6.8 (5.8–8.5) months
$\chi^2$	25.7 ( $P < 0.0001$ )	5.1 ( $P = 0.0235$ )

BPC, Best Physician's Choice;  $\chi^2$ , chi-squared; CI, confidence interval; N/A, not available; OS, overall survival; PFS, progression-free survival.

NovoTTF-100A responders have somewhat different clinical characteristics than BPC responders (Table 1). Notably, five of 14 responders in the NovoTTF-100A cohort, while none of seven responders in the BPC cohort, had prior low-grade histology. Among the NovoTTF-100A responders, there was a trend for increased median and mean OS among those with prior low-grade histology compared to those without, 27.7 and 39.2 (95% CI 19.0–59.4) versus 16.6 and 17.0 (95% CI 9.1–24.9) months, respectively ( $P = 0.0532$ , Fig. 4A). However, the median and mean PFS was significantly prolonged among those with prior low-grade histology compared to those without, 18.0 and 34.4 (95% CI 10.6–58.3) versus 5.5 and 10.7 (95% CI 2.2–19.2) months, respectively ( $P = 0.0278$ , Fig. 4B).

Dexamethasone use among responders was also significantly lower than that in nonresponders (Fig. 5). In both NovoTTF-100A and BPC cohorts, responders had a lower daily dexamethasone usage than nonresponders. For the NovoTTF-100A cohort, the respective median and mean daily dexamethasone dose was 1.0 and 2.3 (95% CI 0.8–3.8) mg for responders versus 5.2 and 6.8 (95% CI 5.6–8.1) mg for nonresponders ( $P = 0.0019$ ). For the BPC chemotherapy cohort, the respective median and mean daily dexamethasone dose was 1.2 and 1.4 (95% CI 0.3–2.4) mg for responders versus 6.0 and 7.2 (95% CI 6.0–8.4) mg for nonresponders ( $P = 0.0041$ ). Notably, the cumulative dexamethasone dose was only found to be significantly lower in responders than nonresponders in the NovoTTF-100A cohort but not in the BPC chemotherapy cohort. For the NovoTTF-100A cohort, the respective median and mean cumulative dexamethasone dose was 7.1 and 35.9 (95% CI N/A–72.5) mg for responders versus 261.7 and 485.6 (95% CI 347.9–623.4) mg for nonresponders ( $P < 0.0001$ ). For the BPC chemotherapy cohort, the respective median and mean cumulative dexamethasone dose was 348.5 and 525.6 (95% CI 96.5–954.7) mg for responders versus 242.3 and 431.0 (95% CI 328.1–533.8) mg for nonresponders ( $P = 0.9520$ ). Therefore, in light of the more frequent low-grade histology and the lower cumulative dexamethasone dose, NovoTTF-100A responders may have more favorable genetic and/or epigenetic characteristics. [Correction added on 30th May 2014, after first online publication: “daily” was amended to “cumulative” in the median and mean dexamethasone dose for the BPC chemotherapy cohort. The same has been amended in the legend of Figure 5, section D.]

### Hazard analysis in responders and nonresponders

The hazard rate of tumor progression initially increased with time, reached a maximum, and then fell to a basal rate in both responders and nonresponders (Fig. 6). However, for NovoTTF-100A responders, the peak hazard

**Figure 2.** Event chart for responders in the NovoTTF-100A and BPC chemotherapy cohorts. Each line represents a single patient and patients are sorted according to the time to response. Transition between states, that is response and failure, are indicated by the corresponding symbols represented on the time line. BPC, Best Physician's Choice.

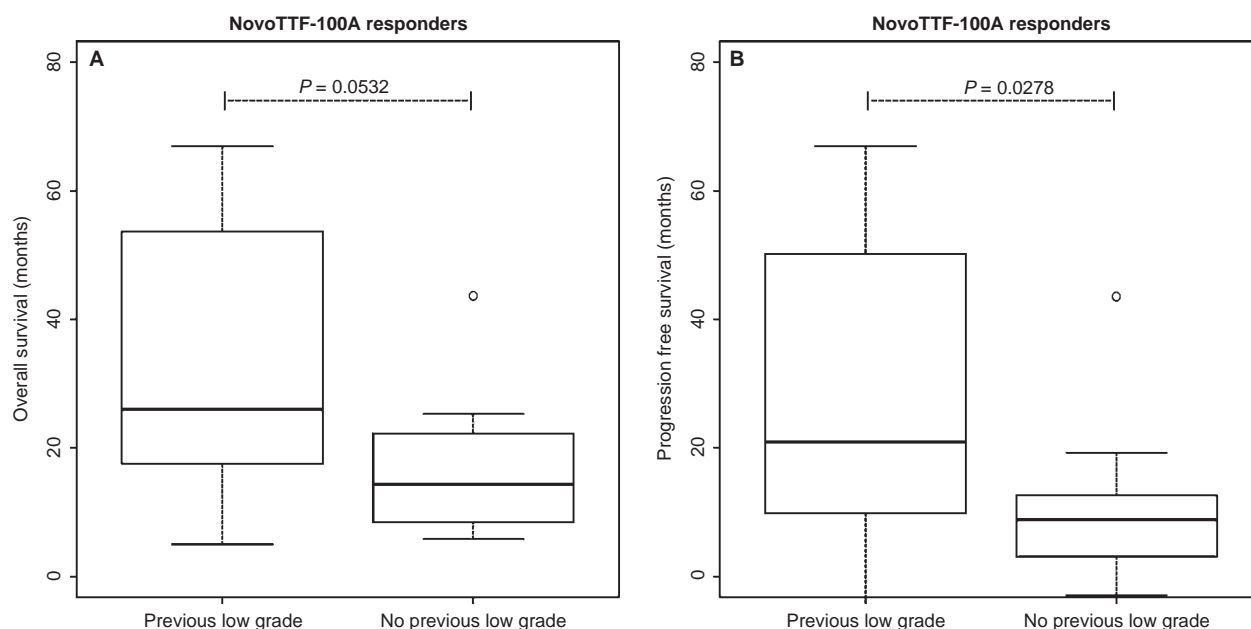

**Figure 3.** MRI from a complete responder treated with NovoTTF-100A monotherapy. Partial response was noted only after 6 months and complete response was noted after 12 months. MRI, magnetic resonance imaging.

rate was lower than that for nonresponders and the time of peak hazard rate was delayed compared to nonresponders. The proportional hazard ratio was 0.1560 (95%

CI 0.0698–0.3500,  $P < 0.0001$ ). In contrast, the BPC cohort's hazard rate for responders peaked higher compared to nonresponders, while the time of peak hazard

**Figure 4.** Box-and-whisker plot of OS and PFS of responders in the NovoTTF-100A cohort with and without prior low-grade glioma histology. (A) The median and mean OS was 27.7 and 39.2 (95% CI 19.0–59.4) months among responders with prior low-grade histology compared to 16.6 and 17.0 (95% CI 9.1–24.9) months among those without prior low-grade histology ( $P = 0.0532$ ). (B) The median and mean PFS was significantly prolonged among responders with prior low-grade histology, 18.0 and 34.4 (95% CI 10.6–58.3) months, compared to those without, 5.5 and 10.7 (95% CI 2.2–19.2) months ( $P = 0.0278$ ). The central boxes represent values from first to third quartile (25–75th percentiles). The horizontal line represents the median and the vertical line extends from the minimum to maximum values and shows the presence of outlier. The outlier was not excluded from analysis. OS, overall survival; PFS, progression-free survival; CI, confidence interval.

rate is also delayed in responders compared to nonresponders. The proportional hazard ratio was 0.0877 (95% CI 0.0208–0.3700,  $P = 0.0009$ ). The results in both cohorts indicate that responders had a delay in tumor progression, but the higher peak hazard rate in the BPC cohort may be due to their tumor progression at nearly simultaneous time.

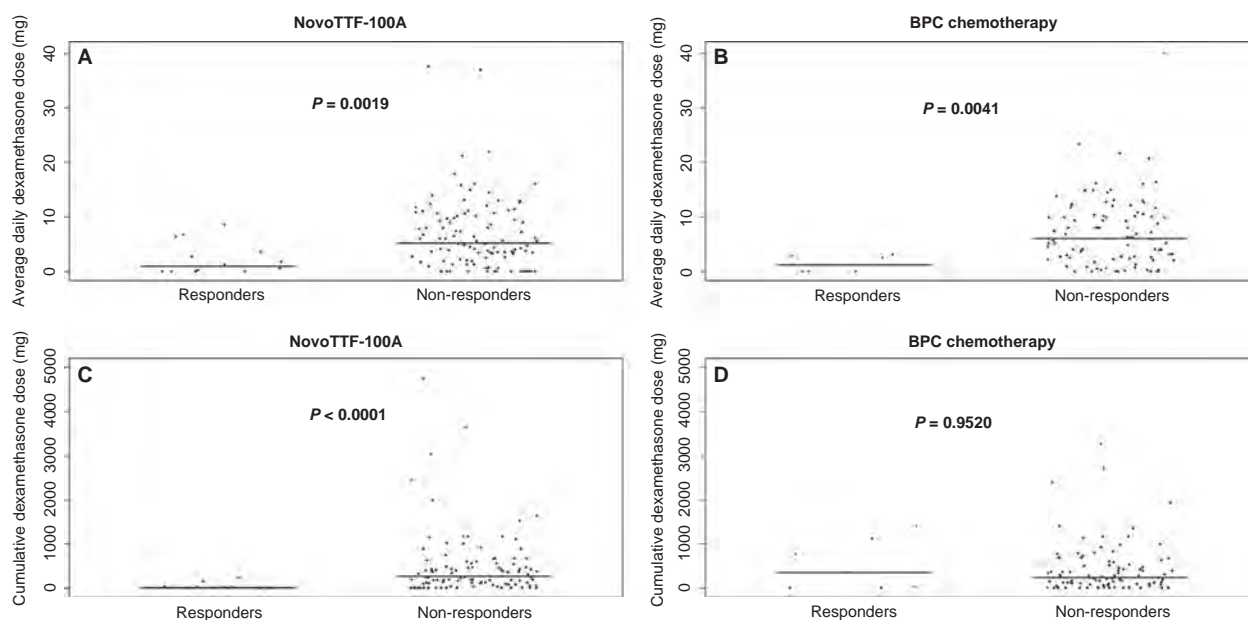

### Survival analysis in responders and nonresponders

Because responders inherently have a longer period of progression-free state due to the presence of the time-to-response state, adjustment is needed to correct the start time when comparing PFS in responders and nonresponders (Table 1 and Fig. 7). Indeed, in unadjusted analyses for both cohorts, responders had marked prolongation of PFS than nonresponders. To correct this apparent bias, we used the Simon–Makuch adjustment to generate conditional PFS plots [17, 18] (Fig. 8). The conditioning time was adjusted based on the Kaplan–Meier estimate of the median time to response in the respective responder groups, or 8.4 months for the NovoTTF-100A versus 5.8 months for the BPC chemotherapy cohort. The adjusted analysis showed that in the NovoTTF-100A

cohort, the median Simon–Makuch conditional PFS was 17.8 (95% CI 11.5–N/A) months for responders and 10.5 (95% CI 10.4–10.6) months for nonresponders ( $\chi^2 = 11.5$ ,  $P = 0.0007$ ). In the BPC chemotherapy cohort, the corresponding conditional PFS was 11.5 (95% CI 11.4–N/A) months for responders and 7.9 (95% CI 7.8–8.6) months for nonresponders ( $\chi^2 = 5.2$ ,  $P = 0.0222$ ). After correcting for bias, responders still had a longer adjusted PFS than nonresponder and this difference was unlikely due to chance. This difference was also notably greater in the NovoTTF-100A than the BPC cohort.

In OS analysis (Fig. 9), responders treated with either NovoTTF-100A or BPC chemotherapy did better than nonresponders. The median OS was 24.8 (95% CI 17.5–N/A) months for responders and 6.2 (95% CI 5.0–7.7) months for nonresponders in the NovoTTF-100A cohort ( $\chi^2 = 25.7$ ,  $P < 0.0001$ ), while it was 20.0 (95% CI 14.5–N/A) months for responders and 6.8 (95% CI 5.8–8.5) months for nonresponders in the BPC cohort ( $\chi^2 = 5.1$ ,  $P = 0.0235$ ). Because responders were expected to live longer than nonresponders, we next asked whether the time to response or the response duration would correlate with OS in either cohort. In the time to response versus OS analysis, the NovoTTF-100A cohort had a linear regression coefficient of  $r^2 = 0.698$  and a Pearson correla-

**Figure 5.** Scatter plot of mean daily dexamethasone and cumulative dexamethasone dose in responders and nonresponders. (A) In the NovoTTF-100A cohort, the respective median and mean daily dexamethasone dose was 1.0 and 2.3 (95% CI 0.8–3.8) mg for responders versus 5.2 and 6.8 (95% CI 5.6–8.1) mg for nonresponders ( $P = 0.0019$ ). (B) In the BPC cohort, the respective median and mean daily dexamethasone dose was 1.2 and 1.4 (95% CI 0.3–2.4) mg for responders versus 6.0 and 7.2 (95% CI 6.0–8.4) mg for nonresponders. (C) In the NovoTTF-100A cohort, the respective median and mean cumulative dexamethasone dose was 7.1 and 35.9 (95% CI N/A–72.5) mg for responders versus 261.7 and 485.6 (95% CI 347.9–623.4) mg for nonresponders ( $P < 0.0001$ ). (D) In the BPC cohort, the respective median and mean cumulative dexamethasone dose was 348.5 and 525.6 (95% CI 96.5–954.7) mg for responders versus 242.3 and 431.0 (95% CI 328.1–533.8) mg for nonresponders ( $P = 0.9520$ ). BPC, Best Physician's Choice; CI, confidence interval; N/A, not available.

tion coefficient of  $\rho = 0.8356$  ( $P = 0.0002$ ), suggesting a strong correlation between these two parameters. No such correlation was seen in the BPC cohort,  $r^2 = 0.217$  and  $\rho = 0.4676$  ( $P = 0.2900$ ). Similarly, in the response duration versus OS analysis, the NovoTTF-100A cohort had a linear regression coefficient of  $r^2 = 0.923$  and a Pearson correlation coefficient of  $\rho = 0.9608$  ( $P < 0.0001$ ). Again, no such correlation was seen in the BPC cohort,  $r^2 = 0.0566$ ,  $\rho = 0.2282$  ( $P = 0.6226$ ). In addition, we used chi-squared distribution analysis to further investigate whether or not there was an association between OS and response. We found no statistical difference between OS and time to response ( $\chi^2 = 336.0$ ,  $P = 0.3114$ ) as well as between OS and response duration ( $\chi^2 = 257.2$ ,  $P = 0.3967$ ), suggesting that OS and response were related parameters. Together, our data indicated that there was a correlation between response and OS and this effect was predominantly seen in the NovoTTF-100A cohort.

## Discussion

Response is typically a secondary endpoint in cancer clinical trials and, when present, it usually signifies antitumor activity. However, bona fide response may or may not correlate with improved survival for recurrent glioblastoma.

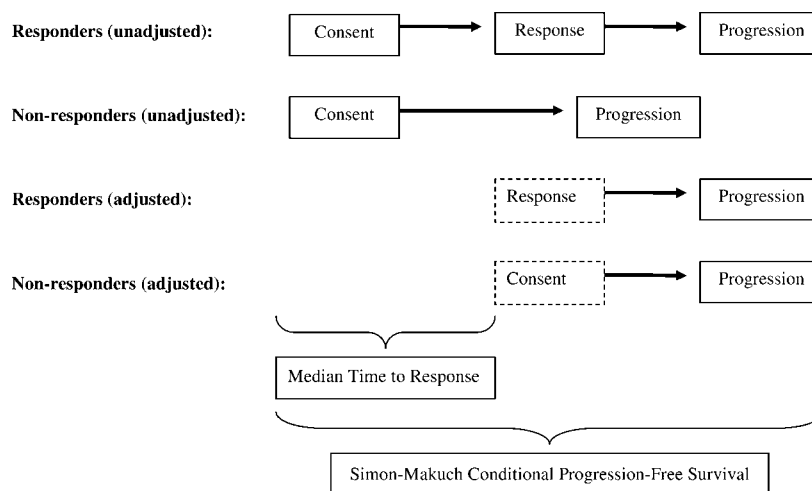

A good example is antiangiogenesis drug like bevacizumab, which has a response rate of 25–60% and a 6-month PFS of 45% primarily from nonrandomized, single-arm phase II trials [3]. However, it has limited impact on OS [4, 5]. In contrast, a randomized trial of temozolomide versus procarbazine detected only six of 112 (5.4%) versus six of 113 (5.3%) responders, respectively, but the PFS and OS at 6 months were significantly different, 21% and 8% versus 60% and 44%, respectively [2]. This lack of concordance between response and survival probably stems from the low efficacy of single-agent cytotoxic chemotherapy against recurrent glioblastoma [19], which has a plethora of resistant clones endowed with genetic and/or epigenetic derangements. Interestingly, bevacizumab was approved for recurrent glioblastoma based on single-arm, phase II response data while temozolomide was rejected despite positive survival data, indicating that response remains important in the overall efficacy analysis.

Our analysis showed that responders in the two cohorts have different clinical characteristics. First, in the prior phase III trial, 10 of 120 (8%) subjects in the NovoTTF-100A cohort and nine of 117 (8%) subjects in the BPC cohort had prior low-grade histologies [11]. However, a significantly higher proportion of NovoTTF-100A

**Figure 6.** The hazard functions for tumor progression in responders and nonresponders. This is a time-dependent estimate of responders that transition out of response into tumor progression or nonresponders that directly transition into tumor progression. (A) In the NovoTTF-100A cohort, the peak hazard rate for responders is lower than that for nonresponders, 0.051 versus 0.069, respectively, and the time of peak hazard rate is delayed in responders compared to nonresponders, 15.1 versus 1.9 months, respectively. (B) In the BPC chemotherapy cohort, the peak hazard rate for responders is higher than that for nonresponders, 0.125 versus 0.047, respectively, but the time of peak hazard rate is still delayed in responders compared to nonresponders, 8.0 versus 3.1 months, respectively. The higher peak hazard rate for responders could be a result of the small sample size ( $N = 7$ ) and/or most patients go into tumor progression at nearly simultaneous time. BPC, Best Physician's Choice.

**Figure 7.** Graphical representation of the adjusted Simon-Makuch conditional PFS. In the intent-to-treat population, PFS is measured from the time of consent until progression or censored event. However, responders pass through a state from consent to response and this time-to-response period introduces a bias in the statistical comparison of responders versus nonresponders, favoring the responder group. To correct this bias, the median time to response is added to both responder and nonresponder groups before comparison of the respective PFS distributions. PFS, progression-free survival.

responders, five of 14 (36%), had prior low-grade histologies while none of seven (0%) BPC responder had this type of histological characteristics, suggesting that

secondary glioblastoma may be more responsive to NovoTTF-100A treatment. Because primary and secondary glioblastomas have different genetic alterations, notably

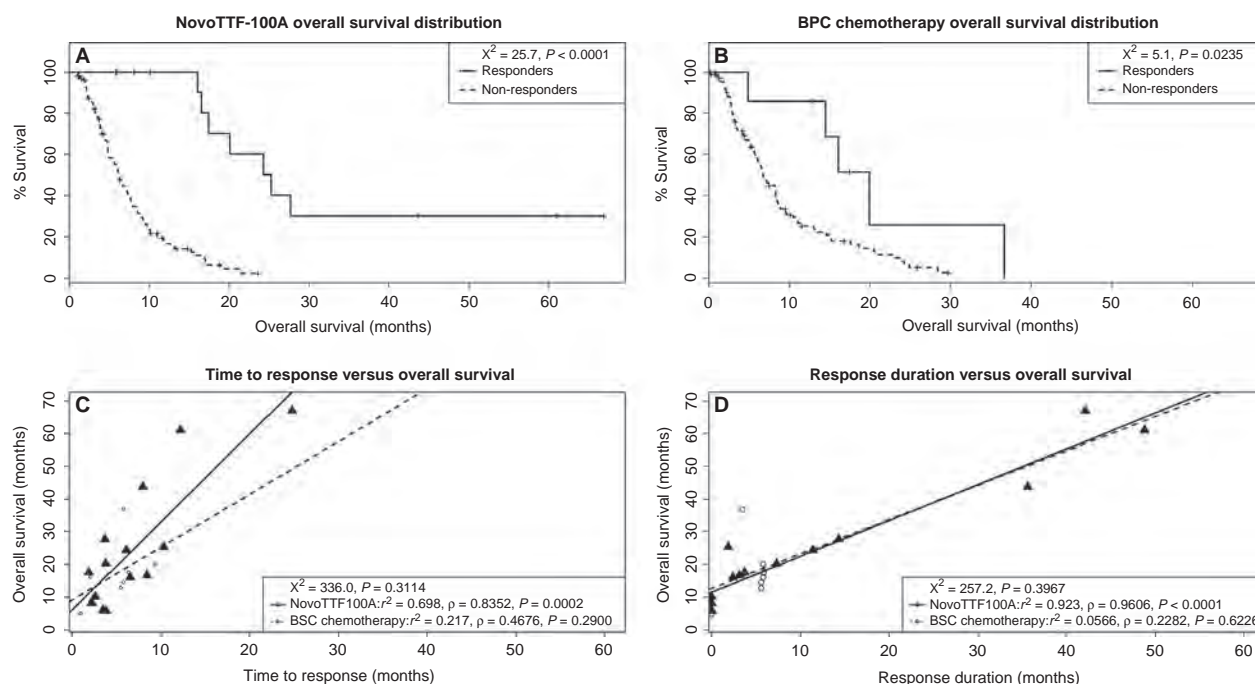

**Figure 8.** Simon-Makuch conditional PFS distribution. The PFS distribution remains significant after adjustment. (A) In the NovoTTF-100A cohort, the median adjusted PFS is 17.8 (95% CI 11.5–N/A) months for responders and 10.5 (95% CI 10.4–10.6) months for nonresponders. Compared to the value before adjustment, the chi-squared distribution between the two groups remained significant at 11.5 ( $P = 0.0007$ ). (B) In the BPC chemotherapy cohort, the median adjusted PFS is 11.5 (95% CI 11.4–N/A) months for responders and 7.9 (95% CI 7.8–8.6) months for nonresponders. Compared to the value before adjustment, the chi-squared distribution between these two groups also remained significant at 5.2 ( $P = 0.0222$ ). PFS, progression-free survival; CI, confidence interval; N/A, not available; BPS, Best Physician's Choice.

*EGFR* and *MDM2* amplifications together with *p16* deletion in primary glioblastomas and *p53* mutation, *IDH1* mutation and *PDGFR* amplification in secondary glioblastomas, the distinct genetic makeup in these two subtypes of glioblastomas could make secondary glioblastomas more susceptible to NovoTTF-100A treatment [20, 21]. In the genomic analysis of glioblastoma subtypes, Verhaak et al. [21] found that the majority of secondary glioblastomas have proneural profiles expressing oligodendrocytic development genes such as *PDGFRA* and *OLIG2*. Notably, the proneural subtype is less responsive to concurrent chemotherapy and radiation than the classical, mesenchymal, and neural subtypes [21]. Similarly, Ducray et al. reported that there was no significant response to neoadjuvant chemotherapy or radiation alone in the proneural glioblastoma while the mesenchymal and classical subtypes were more likely to respond to radiation and chemotherapy, respectively [22]. Therefore, it would be important to determine whether the five NovoTTF-100A responders with previous low-grade histologies also have gene expression profile consistent with the proneural form, as opposed to other subtypes, of glioblastoma. Furthermore, nine of 14 (64%) responders in the

NovoTTF-100A cohort had no prior low-grade histology and the response seen in these patients may suggest that there could be additional genetic and/or epigenetic determinants. Second, the daily dexamethasone dose used by both NovoTTF-100A and BPC chemotherapy responders was significantly lower than that used by nonresponders. Indeed, dexamethasone has been associated with profound immunosuppression and increased risk of infection [23]. More importantly, patients with lower dexamethasone usage may be more able to mount an anticancer immune response against the glioblastoma [24, 25]. Our preclinical data indicate that alternating electric fields stress the cytoplasm of dividing tumor cells and that cause the translocation of calreticulin from the endoplasmic reticulum to the surface of cell membrane [25, 26]. This surface expression of calreticulin could mark the tumor cells for immune destruction. Therefore, this type of antiglioblastoma immune response may be more important for NovoTTF-100A responders than BPC chemotherapy responders, as global immunosuppression by dexamethasone plays a greater role in counteracting the efficacy of NovoTTF-100A than BPC chemotherapy. Taken together, the data on prior low-grade histology

**Figure 9.** Overall survival distribution between responders and nonresponders. (A) In the NovoTTF-100A cohort, the median OS is 24.8 (95% CI 17.5–N/A) months for responders and 6.2 (95% CI 5.0–7.7) months for nonresponders, and the chi-squared distribution between these two groups is significantly different at 25.7 ( $P < 0.0001$ ). (B) In the BPC chemotherapy cohort, the median OS is 20.0 (95% CI 14.5–N/A) months for responders and 6.8 (95% CI 5.8–8.5) months for nonresponders. The chi-squared distribution between these two groups has a smaller difference at 5.1 ( $P = 0.0235$ ). (C) In the NovoTTF-100A cohort, there is linearity and correlation between OS and time to response (linear regression  $r^2 = 0.698$ ; Pearson  $\rho = 0.8352$ ,  $P = 0.0002$ ). However, in the BPC cohort, the linearity and correlation are less robust between OS and time to response (linear regression  $r^2 = 0.217$ ; Pearson  $\rho = 0.4676$ ,  $P = 0.2900$ ). In the chi-squared distribution analysis, there is no statistical difference between OS and time to response ( $\chi^2 = 336.0$ ,  $P = 0.3114$ ), suggesting that OS and time to response are statistically related parameters. (D) In the NovoTTF-100A cohort, there is also linearity and correlation between OS and response duration (linear regression  $r^2 = 0.923$ ; Pearson  $\rho = 0.9606$ ,  $P < 0.0001$ ). However, in the BPC cohort, there is no linearity or correlation between OS and response duration (linear regression  $r^2 = 0.0566$ ; Pearson  $\rho = 0.2282$ ,  $P = 0.6226$ ). In the chi-squared distribution analysis, there is no statistical difference between OS and response duration ( $\chi^2 = 257.2$ ,  $P = 0.3967$ ), suggesting that OS and response duration are statistically related parameters. CI, confidence interval; BPS, Best Physician's Choice; N/A, not available;  $\chi^2$ , chi-squared.

and dexamethasone dose suggest potential underlying genetic and/or epigenetics determinants of NovoTTF-100A response.

The response duration, adjusted Simon–Makuch PFS, and OS favor NovoTTF-100A over BPC chemotherapy. First, responders in our NovoTTF-100A cohort behaved similar to a prior analysis by Hess et al. [18], with the hazard rate peaking lower and later than the nonresponders. However, responders in the BPC cohort peaked markedly higher than nonresponders, which could be a result of near-simultaneous tumor progression. Furthermore, the time interval between peak hazard rates of responders and nonresponders in the BPC cohort is narrower than that for the NovoTTF-100A cohort, suggesting that NovoTTF-100A responders had a slightly more favorable tumor progression profile than BPC chemotherapy responders. Second, Simon and Makuch [17, 18] introduced a correction by adding the median time

to response for every patient in both responder and nonresponder groups and thereby removing the inherent bias in responders when performing survival comparison. Compared to the unadjusted PFS analysis, the Simon–Makuch adjustment showed a smaller but still significant difference in the chi-squared distributions between responders and nonresponders in both NovoTTF-100A and BPC cohorts. Therefore, the difference in PFS between NovoTTF-100A responders and nonresponders remains statistically valid despite the small sample size of responders. Also, this difference is larger in the NovoTTF-100A than the BPC cohort, suggesting that responders possibly experienced a greater efficacy from NovoTTF-100A than responders from BPC chemotherapy. Lastly, we showed an association between survival and response. Our chi-squared analysis cannot reject the null hypothesis that OS versus time to response and OS versus response duration are different in our two cohorts.

Notably, Pearson analysis showed that responders to NovoTTF-100A had a stronger correlation than responders to BPC chemotherapy. Hess et al. [16] used Cox proportional hazard analysis of responders to cytotoxic chemotherapies and also found a correlation between OS and response. Together, these data suggest that NovoTTF-100A responders have longer OS and PFS, but a larger sample size is needed to confirm this finding.

There are multiple challenges facing the development of drug therapies for glioblastoma, including parallel and redundant signaling pathways that subserve the growth and proliferation of the tumor, multiple pharmacodynamic targets, the narrow therapeutic index, propensity for the development of resistance, and pharmacokinetic interference from the blood–brain barrier. Therefore, novel treatments that can overcome these challenges are needed. The NovoTTF-100A device fits this profile because it is a locoregional therapy and thereby lacks systemic side effects. Similar to traditional cytotoxic chemotherapies and newer targeted agents, it also interferes with tumor cell mitosis. Specifically, the alternating electric fields emitted by the device block tumor cell progression from metaphase to anaphase, resulting in chromosomal aneuploidy and cytoplasmic stress that ultimately lead to apoptosis, immunogenic cell death, or both [10, 26]. In this post hoc analysis comparing responders in the NovoTTF-100A and BPC chemotherapy cohorts, we found that secondary glioblastomas and low dexamethasone usage are associated with a higher proportion of NovoTTF-100A responders but not BPC chemotherapy responders. It is notable that in a population-based study performed by Ohgaki et al. [27], secondary glioblastomas appeared to have a slower rate of decline in survival than primary glioblastomas. We speculate that patients whose glioblastomas arose from prior low-grade gliomas may have a slower growth rate than those from primary glioblastomas. When treated with NovoTTF-100A, this slower rate of tumor progression might allow enough time for the efficacy of TTFs to emerge because it may take multiple mitotic cycles to reduce the number of tumor cells and the size of the glioblastoma. This slower rate of growth may not matter as much for BPC chemotherapies due to their direct genomic toxicity. Furthermore, the cytoplasmic stress induced by the alternating electric fields also marks the tumor cells for immunological destruction and clearance [26]. Therefore, removal of immunosuppression in the patient, such as reducing or discontinuing dexamethasone usage, would have a greater effect on those receiving NovoTTF-100A treatment than BPC chemotherapy. Taken together, a possible slower rate of tumor growth in secondary glioblastomas and a reduction in immunosuppression caused by dexamethasone may be

the underlying mechanisms for the higher number of responders observed in the NovoTTF-100A cohort.

Future clinical trials on the NovoTTF-100A device must include stratification of potential predictive factors of response that include both genetic and epigenetic determinants. It is important to note that the genetic makeup of secondary glioblastomas is different from those of primary glioblastomas and these differences may determine whether or not a glioblastoma responds to a specific therapy. Therefore, genetic profiling of the tumor among patients enrolling into future NovoTTF-100A clinical trials would greatly facilitate the identification of those who are likely, as well as others who are unlikely, to respond to treatment. Furthermore, future trials may also need to include immune modulator that may augment the immunological effect of alternating electric fields. Such concerted approach to treatment will hopefully increase the response rate and efficacy of NovoTTF-100A against glioblastoma.

**Abstract** We characterized health-related quality of life (HRQoL), cognitive, and functional status in newly diagnosed glioblastoma (GBM) patients receiving Tumor treating fields (TTFields) with temozolomide (TMZ) versus TMZ alone in a planned interim analysis of a randomized phase III trial [NCT00916409], which showed significant improvement in progression-free and overall survival with TTFields/TMZ. After radiotherapy with concomitant TMZ, newly diagnosed GBM patients were randomized (2:1) to TTFields/TMZ (n = 210) or TMZ (n = 105). Interim analysis was performed in 315 patients with ≥18 months of

follow-up. HRQoL, a secondary endpoint, was evaluated in per-protocol patient population and expressed as change from baseline (CFB) at 3, 6, and 9 months for each subscale in the EORTC QLQ-C30/BN20. Karnofsky performance scores (KPS) and Mini-Mental State Examination scores (MMSE) were assessed. CFB in HRQoL was balanced in treatment groups at the 12-month time point. Initially, HRQoL improved in patients treated with TTFields/TMZ (CFB3: 24% and CFB6: 13%) versus TMZ (CFB3: −7% and CFB6: −17%), though this difference was no longer evident at the 9-month point. General scales, including physical and social functioning, showed no difference at 9 and 12 months. TTFields/TMZ group reported higher concerns of “itchy skin”. KPS over 12 months was just below 90 in both groups. Cognitive status (MMSE) was stable over time. HRQoL, KPS, and MMSE were balanced in both groups over time. There was no preliminary evidence that HRQoL, cognitive, and functional status is adversely affected by the continuous use of TTFields.

## Introduction

Glioblastoma (GBM) is the most aggressive and common malignant primary brain tumor in adults, with an estimated 9600 to 11,200 new cases diagnosed in the US yearly [1]. Patients with GBM have a poor prognosis with median overall survival (OS) of 14.6 months in clinical trial settings and 11 months in general GBM population [2, 3], and patients experience recurrence on average within 7 months despite use of multimodal therapies [3, 4]. Given that novel

treatment approaches for GBM have only offered modest gains in OS and/or progression-free survival (PFS), their role in improving functioning or palliating adverse symptoms has been highlighted, and thus assessment of neurocognitive functioning (NCF) and health-related quality of life (HRQoL) has gained priority in neuro-oncology trials [5].

Quality of life is a multi-faceted construct, encompassing physical, emotional, cognitive, and social functioning, and characterized by patient self-report to reflect a subjective assessment of well-being [6]. In addition to self-report, objective assessment of cognition through validated measures is also recommended, as it has been shown to relate to patients' ability to perform basic and instrumental activities of daily living [7] and to have independent prognostic value for disease progression [8]. A large portion of patients with GBM experience reduced HRQoL, as well as decrement in objectively measured NCF in the pre-treatment setting [9]. Additional decline in HRQoL and NCF typically occurs throughout the course of the disease, secondary to side effects from therapies, tumor recurrence or progression, and disease related complications, such as seizures and venous thromboembolic events [6]. Therefore, measurement of HRQoL and NCF, as well as patient functional status via the Karnofsky Performance Score (KPS) at multiple time points have become standard in clinical trials for novel therapeutic approaches targeting glioma [5]. Furthermore, data regarding quality of life and cognition are factored into drug-efficacy metrics and can in turn inform physician and patient decision-making regarding choices of treatment [6].

Current standard-of-care treatment for newly diagnosed GBM includes maximum safe resection or biopsy and adjuvant concomitant radiation with temozolomide (TMZ) during the induction phase, followed by monthly TMZ for 6–12 months [3, 10]. Tumor Treating Fields (TTFields, Optune, Novocure, Ltd., Haifa, Israel) is a novel cancer therapy that leads to mitotic arrest and apoptosis of dividing cells by disrupting mitotic spindle formation during metaphase [11] and causing dielectrophoretic movement of polar molecules during cytokinesis [12]. The results from a randomized phase III trial (EF-11) comparing its efficacy with regard to extending OS and PFS in recurrent GBM in comparison to best physician chosen chemotherapy have been previously published [13]. Data from the trial indicated superior HRQoL for the TTFields group, pertaining to self-ratings of cognitive and emotional functioning in particular, as well as with regard to treatment related toxicity (appetite loss, constipation, diarrhea, nausea, and vomiting were more prevalent in the chemotherapy-treated arm). Most recently, a randomized phase III clinical trial (NCT00916409) for newly diagnosed GBM comparing TTFields/ TMZ versus TMZ alone has demonstrated superior outcomes of the treatment arm versus control arm in both OS and PFS at the pre-planned interim analysis time point [14]. This report focuses

on the findings detailing HRQoL, cognitive, and functional status in the same trial.

## Patients and methods

Full study details have been published previously [14]. Briefly, patients with newly diagnosed supratentorial GBM, age 18 and above, with KPS score of 70 or higher, with adequate bone marrow, liver, and renal functions were eligible for this trial. Patients were randomized at a ratio of 2:1 to receive TTFields/TMZ versus TMZ alone. Treatment with TTFields was initiated within 4–7 weeks from the last dose of the concomitant TMZ and radiation therapy. Randomization was performed through a central web-based randomization system and was stratified by extent of resection and O6-methyl guanine DNA methyltransferase (MGMT) gene methylation status. Raw scores on the HRQoL measures were normalized (range 0–100). A change of 10 points on a scale in either direction was regarded as the minimal clinically significant change [15].

Patients in the TTFields/TMZ group received continuous TTFields combined with cyclic TMZ per standard of care. TTFields was administered via placement of two pairs of transducer arrays on shaved scalp according to an individualized array map based on patient magnetic resonance imaging (MRI) and tumor location(s). The transducer array map was generated using mapping software designed for optimization of field intensity within the treated tumor (NovoTAL®, Novocure Ltd). The TTFields generate 200 kHz alternating electric fields within the brain. Following training in array placement, patients were supplied with transducer arrays in sterile packaging in order to replace arrays at home every 3 days. It was recommended that patients use the TTFields continuously to reach a goal of an average of 18 h per 24 h in a 4 week period; short treatment breaks were allowed. For those with tumor progression, second-line chemotherapy was offered per choice of the treating physician. In the TTFields/TMZ group, TTFields could be maintained until a second radiological progression or a maximum of 24 months. The study was approved by institutional review boards of all 83 participating institutions. All patients had reviewed and signed informed consent prior to enrollment in the study.

## Procedures

At baseline, in addition to undergoing contrast-enhanced MRI of the brain (within 2 weeks prior to the start of treatment), comprehensive assessments were performed (within 1 week of treatment initiation) including physical and neurological examinations, collection of laboratory parameters, and measurement of patient independence in

activities of daily living with the KPS. Patients completed questionnaires assessing HRQoL and cognitive screening with the Mini-Mental Status Exam (MMSE) [16]. HRQoL was assessed with an EORTC quality-of-life questionnaire core-30 (QLQ-C30, Version 3), supplemented by the brain cancer module (BN20). Thereafter, MMSE and KPS assessments were repeated once monthly during office visits, and the HRQoL questionnaires were administered once every 3 months until progression or withdrawal from the trial.

The EORTC quality of life questionnaire C30 (EORTC QLQ-C30) is a general 30-item core measure used in many multi-national clinical trials with cancer patients [6] and is supplemented by the EORTC QLQ Brain Neoplasm 20 (BN20), which was developed specifically for patients with brain cancer. Robust reliability and validity have been established for both measures [17, 18]. Subscales within the EORTC QLQ-C30 include: (a) five functional scales—physical, role, emotional, cognitive, and social, as well as a global health status rating; (b) three symptoms scales—nausea, vomiting, and fatigue; and (c) six single-item scales—insomnia, appetite loss, constipation, diarrhea, dyspnea, and financial effect of tumor/treatment. The BN20 comprises four domain scores: visual disorder, motor dysfunction, communication deficit, and future uncertainty, and seven individual symptom items: seizures, difficulty with bladder control, weakness in legs, headache, drowsiness, hair loss, and itching. All measures were scored in accordance with the recommended standardized approach [19]. For the EORTC QLQ-C30, a higher positive score on a functional scale or on the global health status scale represents improved functioning, whereas higher scores on symptom scales and single item scales represent a high level of symptomatology/difficulty.

The MMSE is a brief cognitive screening measure that has been translated into multiple languages and is designed to sample orientation (place and time), registration, attention, recall, language, and visual construction with a maximum total score of 30 points [20]. It has been shown to have acceptable reliability and validity in patients with dementia, though lower reliability values have been recorded in relatively “healthy” community samples [20]. A cut-off of 27 points was chosen to discriminate between cognitively impaired versus cognitively intact participants in accordance with findings among individuals of Caucasian background with higher levels of education [21].

Prospective recording of adverse events was implemented in accordance with the National Cancer Institute’s Common Terminology Criteria (version 3.0) and began from initiation of treatment of either TTF/TMZ or TMZ alone until 2 months after discontinuation of treatment. The descriptive interim findings with regard to presence of adverse events in each study group have been reported previously [14].

Given that cognitive status, functional status, and health-related quality of life were secondary endpoints of the EF-14 trial, analysis was performed on the per protocol patient population: TTFields/TMZ (n = 196) and TMZ alone (n = 84). Descriptive data was expressed as change from baseline (CFB), which was calculated for each time point over the course of the first year post-randomization, and is presented in the “Results” section.

## Results

A total of 695 patients diagnosed with supratentorial GBM were randomized (2:1 ratio) to receive either TTFields/TMZ or TMZ alone between July 2009 and November 2014. As pre-specified, the interim analysis was performed when 210 and 105 patients were randomized to the TTFields/TMZ and TMZ alone, respectively, with a median follow-up of 38 months (range 18–60 months) (Fig. 1). The median time from randomization to treatment was 37 days (from the last day of radiotherapy to randomization). As the pre-defined boundaries for trial success (improvement of both PFS and OS) were met, the independent data and safety monitoring committee at the October 2014 meeting recommended termination of the study. The US Food and Drug Administration approved study termination; recruitment closed on November 29, 2014, when 695 of the planned 700 patients were enrolled. Patients in the TMZ alone arm were allowed to cross over to receive TTFields and follow-up of all patients continued in accordance with study protocol.

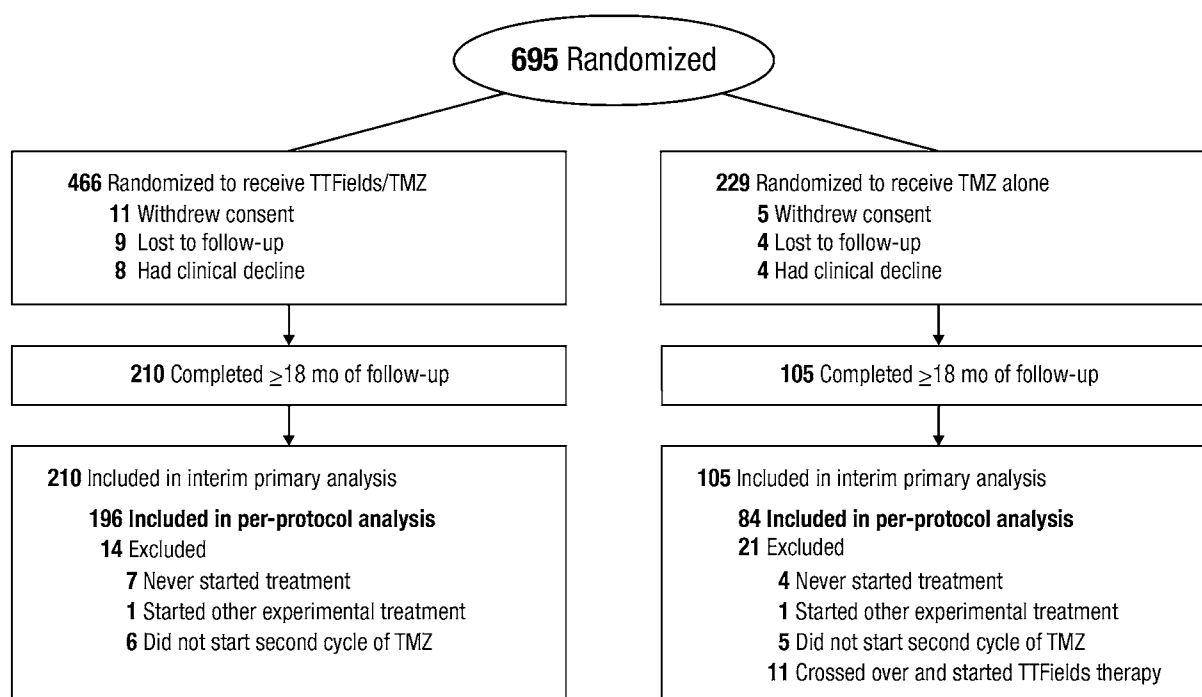

Patient baseline characteristics at interim analysis were well balanced between the two treatment groups (Table 1) [14]. Median age was 57 years and 66% were male. Tumor location was similar across groups. A gross total resection was achieved for 64% of the participants in each group, whereas about 11% had a biopsy in each arm. Use of anti-epileptic medication and corticosteroid therapy was comparable across the two groups. Median KPS score at baseline was 90 for each group. Based on MMSE scores at baseline, 15 and 13% were classified as cognitively impaired at baseline in the TTFields/TMZ and TMZ groups, respectively.

HRQoL assessment was a secondary endpoint of the study and was analyzed in the per protocol population. Compliance with questionnaire (EORTC QLQ-C30 and BN20) completion was 82% (173/210) in the TTFields/TMZ group and 64% (67/105) in the TMZ alone group. All assessments were carried out until the number of remaining patients was  $\leq 70$ .

### Functional and cognitive status

KPS ratings at baseline and monthly thereafter reflected relative stability with regard to patient independence in activities

**Fig. 1** Patient flow**Table 1** Baseline characteristics (per protocol population)

Baseline characteristics	TTFields/TMZ (n = 196) n (% or range)	TMZ (n = 84) n (% or range)
Age: median (range)	57 (20–83)	58 (21–80)
Sex: M/F	133/63 (67.9/32.1)	54/30 (64.3/35.7)
KPS: median (range)	90 (60–90)	90 (70–100)
Time from diagnosis to randomization (days)	116 (59–171)	113 (43–170)
Tumor location		
Both	2 (1.0)	1 (1.2)
Corpus Callosum	8 (4.1)	3 (3.6)
Left	87 (44.4)	32 (38.1)
Right	99 (50.5)	48 (57.1)
Extent of resection		
Biopsy	21 (10.7)	10 (11.9)
Gross total resection	127 (64.8)	54 (64.3)
Partial resection	48 (24.5)	20 (23.8)
Cycles of TMZ (Median and range)	6 (1–26)	4 (1–24)
Cycles of TTFields	9 (1–58)	0 (0)

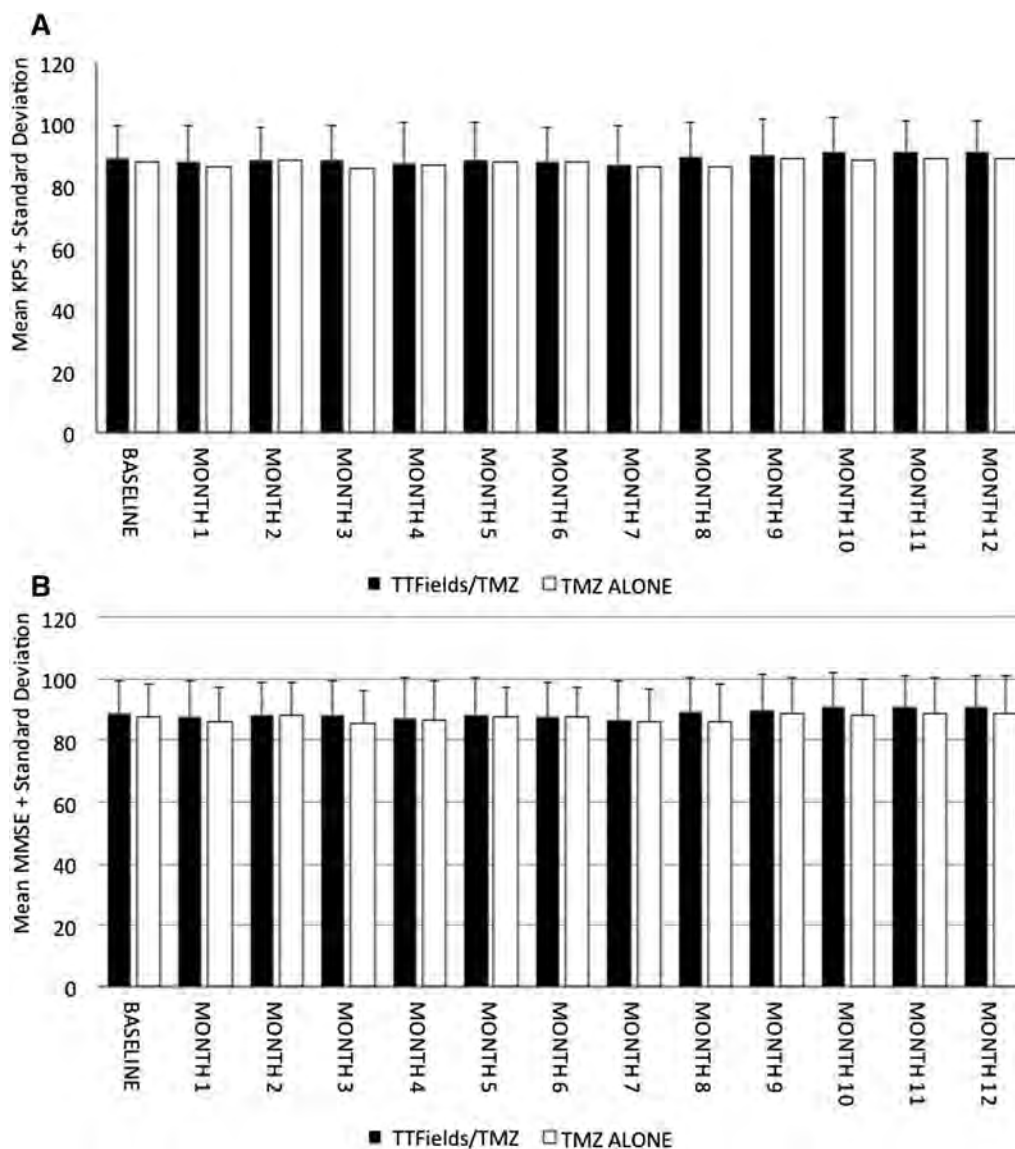

of daily living over time during the first year after randomization in either group; the majority of mean scores remained just under 90 (Fig. 2a). Mean percentage change from baseline (CFB) was between −4.3 (month 7) and −1.6 (month 1) within the TTFields/TMZ group and between −4.2 (month

8) and −0.4 (month 2) in the TMZ alone group. Similarly, mean cognitive status within either group did not decline below 27/30 and no differences in MMSE scores were documented between the groups (Fig. 2b). Mean percentage change in MMSE scores ranged from −2.4 (month 1) to 4.8 (month 8) in the TTFields/TMZ arm, and from −0.5 (month 2) to 3.8 (month 8) in the TMZ alone group.

### Health-related quality of life (HRQoL)

At 3 and 6 months, HRQoL initially improved in patients treated with TTFields/TMZ (CFB3: 24% and CFB6: 13%) versus mild reduction in the TMZ group (CFB3: −7% and CFB6: −17%). However, at 9 months the CFB were 0.42 (2.9%) in the TTFields/TMZ group, and 0.0 (7.8%) in the TMZ group (Fig. 3). There were no significant changes registered from baseline values on any of the quality-of-life scales (Fig. 4). No significant group differences were reported for any of the functional scales from the EORTC QLQ-C30 measure. Patients did not rate their physical or social functioning any differently when receiving TTFields/TMZ versus TMZ alone. Group differences were pronounced for “itchy skin,” where patients receiving TTFields/TMZ had higher numeric scores (Fig. 5). Self-reported neurologic symptomatology on BN20 did not differ between the two groups and as expected reflected a tendency toward increase in symptoms, likely related to known side effects of TMZ, which was administered to both groups.

**Fig. 2** Mean changes in KPS (a) and MMSE (b) over 12 months with TTFields/TMZ versus TMZ alone. (Per Protocol Population)

## Discussion

The current study reviewed available data at the interim analysis from the first multicenter international phase III clinical trial of TTFields added to standard-of-care therapies in patients with newly diagnosed glioblastoma (EF-14). Although findings characterizing the efficacy of TTFields with regard to OS and PFS have been encouraging and were published elsewhere [14], this is the first report of cognitive status, self-reported HRQoL and performance status at the pre-planned interim analysis of the trial. As such, the data presented herein may offer important implications for the provision of clinical care to individuals with newly diagnosed glioblastoma and their families and highlights directions for future study.

Interim review of the data revealed no significant group differences across any of the administered measures, including mean cognitive status, KPS-assessed functional status, and HRQoL. Results indicated that patients receiving TTFields/TMZ and TMZ alone, on average, had intact cognitive status (all means stayed above the 27-point cut-off for both groups) and were independent with regard to functional status (KPS mean scores at 3, 6, 9, and 12 months following randomization remained just below 90). Mean self-reported functional scales from the EORTC QLQ-C30 did not differ between the two groups, including self-ratings of social functioning and physical functioning, which could theoretically be adversely impacted by wearing the TTFields device. Findings from the cognitive screening (MMSE) showing no adverse change in cognitive status were congruent with

**Fig. 3** Changes from baseline (%) in Global Health Status from baseline to 9 months with TTFields/TMZ versus TMZ alone. (Per Protocol Population). An increase in percentage corresponds to an increase in QoL

results from HRQoL measures revealing no significant CFB in self-ratings of cognitive functioning. Similarly, self-reported emotional functioning was also not significantly different relative to baseline in both groups at months 3, 6, and 9. Although symptoms known to be associated with TMZ treatment (e.g., nausea/vomiting, diarrhea, constipation, appetite loss, fatigue and pain) were reported by both groups, no differences were noted between treatment groups.

The present HRQoL findings are consistent with results from the previous phase III trial (EF-11) assessing efficacy and HRQoL in patients with recurrent GBM treated with TTFields versus physician best choice chemotherapy [13]. Similarly, there were no differences between the TTFields

group and patients receiving chemotherapy on self-ratings of global health and social functioning; ratings of cognitive and emotional functioning were higher in the TTFields group, and role functioning favored TTFields. In addition, pain and fatigue were increased only in the chemotherapy patients, but not in the patients receiving TTFields.

Limitations inherent in the design of the current clinical trial have been addressed elsewhere and comprise: exclusion of patients with very poor prognoses due to the timing of randomization; reporting bias given that patients in the TTFields group were allowed to remain in the trial beyond progression; and absence of a sham/placebo treatment [14]. Compliance with questionnaire (EORTC QLQ-C30 and BN20) completion was 82% (173/210) in the TTFields/TMZ group and 64% (67/105) in the TMZ alone group due to more patients in the TMZ arm withdrawing consent after GBM progression to participate in other trials, whereas patients in the TTFields/TMZ arm continued treatment and clinical follow up with MMSE and KPS collected monthly during office visits, and HRQoL questionnaires completed every 3 months until a second progression. It can be extrapolated that missing data from noncompliant participants in the TMZ group would likely skew toward poorer ratings for HRQoL and reduced cognitive status, given findings of declining functioning with advancement of disease. Nevertheless, increased efforts to collect HRQoL data, and perform cognitive screening and assessment of functional status as participants exit the trial, in addition to the measurements collected at assigned study time intervals, are recommended in order to provide more complete comparisons between treatment modalities.

The use of the MMSE to measure cognition in clinical trials of patients with primary brain tumor has been questioned on grounds of poor sensitivity, potential practice effects with

**Fig. 4** QLQ-C30 Global Health Status and General Scales in TTFields/TMZ versus TMZ alone groups over 12 months in Per Protocol Population. EORTC QLQ-C30, European Organisation for

Research and Treatment of Cancer Quality of Life Questionnaire-C30; SD standard deviation, TMZ temozolomide, QoL quality of life

**Fig. 5** QLQ-C30 Symptom Scales in TTFIELDS/TMZ versus TMZ alone groups over 12 months in Per Protocol Population. An increase in percentage corresponds to a decrease in QoL

repeated administration, and the failure to adequately sample frontal subcortical functions impacted by radiotherapy [22]. Brevity, low cost, and ease of administration during a typical office visit has contributed to wide utilization of MMSE in multiple phase II and phase III clinical trials. It is noted that, had the current study utilized neurocognitive measures with higher sensitivity, as has been suggested in other work [23, 24], greater decline from baseline in cognition may have been documented in both treatment groups, consistent with levels registered in other investigations. The MMSE has been demonstrated to capture cognitive status deterioration in patients receiving escalating doses of radiation [23], hypofractionated radiation with TMZ [24], as well as in patients experiencing first progression of GBM while enrolled in a bevacizumab plus standard-of-care clinical trial [25]. MMSE scores have also been shown to correlate to scales assessing activities of daily living [25]. Nevertheless, given the demonstrated feasibility of more sensitive neurocognitive measures and explicit recommendations by the International Cognition and Cancer Task Force [26], further investigation of potential neurocognitive impact of TTFIELDS on patients with GBM is warranted in future studies. In addition, in light of the high KPS and MMSE scores recorded in both treatment groups in the present study, future investigations in patients with GBM where cognitive deficits may range from very subtle to severe are cautioned to exercise care in employing neurocognitive tests with demonstrated sensitivity to milder decline in cognitive and performance status.

In summary, prospective measurement of HRQoL and neurocognitive functioning as part of clinical trials evaluating novel treatments for GBM has become standard in recent years. It is critical to adequately monitor treatment-related cytotoxicity and provide a multifaceted assessment of the impact of the illness and treatments on patient daily functioning, particularly in light of the limited survival duration for these individuals. As further advances are made in the GBM treatment arena, such data would be essential in providing guidelines regarding expected side effects and informing physician and patient choices of preferred treatment modality.

**Acknowledgements** We are very grateful to patients and their families for participating in the trial as well as to all the EF-14 investigators and their research staff for taking care of the patients. We are very appreciative of Dr. Katherine Tiku's assistance in preparation of this manuscript.

# Tumor Treating Fields

Laura Benson

This chapter provides an understanding of the science of Tumor Treating Fields (TTFields), an innovative antimitotic therapy used to treat solid tumors. The mechanism of action, the delivery system, and the use of TTFields are addressed, as are the prevention and management of side effects and the importance of patient adherence to optimize outcomes when using this therapeutic device.

## Definition of TTFields

TTFields are low-intensity alternating electric fields within the intermediate frequency range. TTFields disrupt cell division through physical interactions with key molecules during mitosis. This mechanism is grounded in the properties of physics that exploit the inherent attributes of cellular components (Kirson et al., 2004). Specifically, TTFields take advantage of the electrical characteristics, geometrical shape, and replication rate of dividing cancer cells, all of which make them susceptible to the effects of frequency-tuned alternating electric fields. TTFields therapy is unlike any other previous applications of electricity in medicine. TTFields therapy does not deliver electric current to tissue, stimulate nerves or muscles, or heat tissue (Kirson et al., 2009).

## Mechanism of Action

TTFields exert an anticancer effect through a multipronged mechanism of action. TTFields therapy creates an alternating electric field within the tumor that attracts and repels the charged components of the cells during mitosis at intermediate frequencies of 100 to 300 kHz and at an intensity of approximately 1 V/cm, TTFields. This alternating field acts at multiple phases of the cell cycle (see figure below):

- It disrupts normal mitotic spindle assembly during metaphase, which leads to mitotic arrest and subsequent apoptosis (Giladi et al., 2014a).
- It produces nonuniform electric fields within dividing cells that exerts a force known as *dielectrophoresis*. This force within the electric fields affects intracellular components such as organelles and macromolecules. During mitosis, the effect of dielectrophoresis pushes the cell parts toward the cell cleavage furrow and interferes with normal cell division cytokinesis.
- It disrupts normal cell division, causing abnormal chromosomal segregation and multinucleation and thereby reducing the clonogenic potential in cellular progeny (see figure below).

Metaphase

Anaphase

Telophase

**Mechanism of action of TTFields.** (© 2015 Novocure. All rights reserved.)

**TTFields impair normal cell nuclear division.** This causes abnormal chromosomal segregation (example showing abnormalities in chromosome 7). (© 2015 Novocure. All rights reserved.)

- It induces mitotic catastrophe (i.e., a major cell disruption during mitosis), which eventually leads to apoptotic cell death.
- It induces endoplasmic reticulum (ER) stress pathways and increases the expression of proteins known to activate immunogenic cell death.
- It impair a cell's ability to repair DNA damage caused by exposure to radiation.

TTFields therapy is a regional anticancer modality with no half-life or impediment posed by the blood-brain barrier, thus sparing off-target systemic adverse effects. TTFields are frequency tuned to exert a maximal cytotoxic effect on specific cancer cell types, sparing normal healthy cells. Different cell lines exhibit maximal proliferation reduction at different frequencies (Kirson et al., 2007). For example, glioma cells exhibit the greatest reduction in proliferation at a frequency of 200 kHz (Kirson et al., 2007), whereas for non-small cell lung cancer (NSCLC) cells, the greatest reduction in cell proliferation is at 150 kHz (see table below) (Giladi et al., 2014b). Efficacy is dose dependent; cytotoxic effects increase when the electric field intensity increases. Threshold value, below which cells are largely unaffected, is approximately 1 V/cm. Unlike drug therapy, TTFields deliver therapy only while activated.

### Efficacy of TTFields Is Frequency Dependent

Tumor Cell Line	TTFields Frequency for Greatest Reduction in Cell Proliferation (kHz)
Glioma	200
Meningioma	200
Non-small cell lung cancer	150
Ovarian	200
Pancreatic	150

### TTFields Therapy System

Optune (Novocure Inc., Portsmouth, NH), formerly called the NovoTTF-100A System, is a medical device approved in the United States and Japan for use as monotherapy for the treatment of recurrent glioblastoma (GBM). Optune is a CE Marked device that is cleared for sale in the European Union, Switzerland, Australia, and Israel for glioblastoma and NSCLC. The complete TTFields therapy delivery system includes an electric field generator; insulated transducer arrays; portable, rechargeable batteries; battery charger; plug-in power supply; connection cable; and carrying case (see figure in next column) (Optune, 2014). Ongoing therapy is patient administered in the home after prescription by a certified health care provider. The U.S. Food and Drug Administration (FDA) mandates that prescribers of

this therapy successfully complete a certification course provided by the manufacturer. The patient is monitored in the outpatient setting by the oncology team on a regular basis. During the course of therapy, patients receive replacement system parts, most often the transducer arrays, from the manufacturer. When the therapy is discontinued, the system is returned to the manufacturer.

Optune medical device. (© 2016 Novocure. All rights reserved.)

Cell response to TTFields is direction dependent. The cells that divide parallel to the electric field show higher rates of damage than those dividing perpendicular to the field (Kirson et al., 2004). Therefore, to maximize the clinical effects, TTFields are delivered noninvasively via two pairs of transducer arrays that produce two perpendicular electric fields. These arrays are applied directly on the surface of the skin in the region surrounding the tumor. TTFields are frequency-tuned to the targeted histology, and during treatment, generation of the electric field switches between the two pairs of arrays at a rate of approximately once per second.

Each array comprises nine insulated ceramic discs (see lower left part of figure on page 172) which have a high dielectric constant, are biocompatible, and are soldered to a flexible circuit board. These discs are separated from the skin by a layer of conductive hydrogel. To keep the arrays in place on the scalp and in continuous direct contact with the skin, the ceramic discs, hydrogel, and circuitry are attached to a hypoallergenic medical adhesive bandage (Lacouture et al., 2014). TTFields therapy should not be used in patients with GBM who have an active implanted medical device, a skull defect, or bullet fragments (Optune, 2014).

A wire from each array plugs into the connection cable, which then plugs into the portion of the device that generates TTFields. Patients may describe a "warm sensation" under the transducer arrays. Each array has eight temperature sensors that monitor temperature; the device will shut off and sound an alarm if array temperature exceeds 41° C (105.8° F), well below the threshold for a thermal skin burn (Lacouture et al., 2014).

In patients with GBM, transducer array placement is based on the results of magnetic resonance imaging. The array locations on a patient's shaved scalp are calculated with the use of FDA-approved simulation software (NovoTAL, Novocure) that optimizes field intensity within the tumor, based on head size and tumor location (see figure below) (Lacouture et al., 2014). Treatment parameters are preset at 200 kHz and a minimal field intensity of 0.7 V/cm in the brain. Neither the health care provider nor the patient needs to make electrical adjustments (Lacouture et al., 2014). Responses to TTFields therapy are typically observed on radiographic evaluations 3 to 5 months after treatment initiation (Vymazal et al., 2014).

Transducer array placement is guided by a patient's MRI results. (© 2016 Novocure. All rights reserved.)

### TTFields Therapy for Recurrent Glioblastoma

In 2011, TTFields therapy was approved by the FDA for use in adults (22 years of age or older) who have recurrent GBM in the supratentorial region of the brain after receiving chemotherapy and whose disease is refractory to surgical and radiation treatment options. The pivotal phase III trial that led to FDA approval in recurrent GBM demonstrated comparable median overall survival time with TTFields therapy compared with chemotherapy, including bevacizumab (Stupp et al., 2012). TTFields therapy was found to be as effective as chemotherapy, with fewer side effects. In addition, patients reported a better quality of life, including improved cognitive and emotional functioning, compared with patients receiving chemotherapy (Stupp et al., 2012). Treatment adherence, or time on therapy, has proved to be an important factor in treatment outcomes. Analysis of the pivotal phase III trial for recurrent GBM showed that an adherence rate of at least 75%, or approximately 18 hours/day, was a clear predictor of survival (Gutin & Wong, 2012; Mrugala et al., 2014; Optune, 2014).

In the Patient Registry Dataset (PRiDe), a postmarketing registry of all commercially treated patients with recurrent GBM receiving TTFields, median overall survival significantly exceeded that observed in the pivotal trial. Favorable

prognostic factors included use in first recurrence, no prior exposure to bevacizumab, and high performance status (Mrugala et al., 2014).

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology for Central Nervous System Cancers indicate that physicians should consider TTFields therapy for patients with GBM who experience recurrence or progression after initial treatment (category 2B) (NCCN, 2015).

### Newly Diagnosed GBM

When combined with temozolomide in human glioma cell line studies, TTFields were found to exert additive cytotoxic effects. This provided the rationale for a phase III trial in patients with newly diagnosed GBM who had completed standard-of-care concomitant chemoradiotherapy. Patients were randomly assigned in a 2:1 ratio to receive either adjuvant temozolomide chemotherapy alone or temozolomide in combination with TTFields therapy (200 kHz). The primary end point was progression-free survival; secondary end points were overall survival, safety, cognitive function, and quality of life. Based on a prespecified interim analysis of 315 patients, the trial was closed early. The first analysis of the full dataset of 700 patients randomized in the trial found progression-free survival to be 7.1 months for the combined therapy versus 4.0 months for temozolomide alone. Overall survival was 20.5 versus 15.6 months, respectively. This translated into 2-year survival rates of 43% for combined therapy with temozolomide and TTFields, compared with 29% for temozolomide alone. No significant added toxicity was observed with the addition of TTFields. Quality of life and gross cognitive function were comparable in both study arms (Stupp et al., 2014; Stupp et al., 2015). Based on these results U.S. FDA has approved Optune in combination with temozolomide for the treatment of adult patients with newly diagnosed GBM.

### Patient and Caregiver Education Before TTFields Therapy

Because TTFields is a continuous, at-home therapy, patient and caregiver education is important. Patients and caregivers should have a basic understanding of the mechanism of action, the system parts and functions, proper use of the equipment, and the importance of compliance with therapy. TTFields therapy is delivered only when the system is in place and activated; therefore, the device is portable and designed to be worn continuously, around the clock. Patient adherence is critical because greater time on therapy is linked to better outcomes (Mrugala et al., 2014). Therefore, patient teaching, ongoing assessments, and continued motivation of patients and their caregivers are key to maximizing the potential benefits received from TTFields therapy. Education on skin preparation and care, prevention and management of side effects, and what to expect during treatment is essential.

### Patient Teaching

Patients should use TTFields only after being trained by qualified personnel who have completed a training course (Optune, 2014). This includes instruction about caring for the system components, how best to prevent and manage skin irritation, and the importance of treatment adherence.

It is important for the family to understand that electric field therapy is not hazardous to those in close proximity to the patient. The electric fields do not contain radiation or pose a hazard to others.

Patients are instructed to remove the transducer array portion of the system every 4 to 7 days to re-shave the head and reapply the transducer arrays. The four transducer arrays that are placed on the scalp need to be replaced every 4 to 7 days and are for single use only. Used system parts (e.g., transducer arrays) are returned to the manufacturer for disposal. Practical tips on how to complete activities of daily living are taught. For example, the patient is taught how to shower without removing the transducer arrays by using a shower cap for bathing.

The delivery system is portable, allowing patients to go about their daily activities while receiving treatment (see figure below). Patients can spend time with family, work, travel, and generally engage in their usual activities, including showering or bathing.

Simulation of patient receiving TTFields therapy for GBM. (© 2016 Novocure. All rights reserved.)

Because treatment is delivered via a visible, constantly present device, support and dedication by both the patient and caregiver are critical to a successful outcome. The transducer

arrays must be changed one or two times per week (i.e., every 4 to 7 days). The time between changes varies based on factors such as sweating, hair growth, and weather. The patient and caregiver are taught this procedure at the start of therapy.

### Side-Effect Profile

Device-related adverse events can impact a patient's quality of life, affect adherence to therapy, and contribute to medical costs (Lacouture et al., 2014). The most commonly occurring adverse event associated with the use of TTFields therapy is skin irritation, largely grade 2 (mild to moderate), under the transducer arrays (see figure below). The types and potential causes of dermatologic adverse events are summarized in the table below, and the signs of skin events based on underlying pathogenesis in the table on page 176.

Prophylactic strategies to prevent skin irritation include proper shaving with an electric razor and avoiding the placement of ceramic discs directly over postsurgical screws or plates (Lacouture et al., 2014). Patients are taught how to properly shave and how to adjust the placement of the transducer arrays; they are advised to assess skin condition every 4 to 7 days. The table on page 176 highlights what the patient and caregiver can do to prevent dermatologic adverse events.

**Skin irritation.** Dermatologic erosions and skin infection (folliculitis) in a 60-year-old man who had been receiving temozolomide and NovoTTF Therapy for 3 months. (© 2016 Novocure. All rights reserved.)

### Types and Potential Causes of Dermatologic Adverse Events

Adverse Event	Potential Cause
Irritant contact dermatitis	Chemical irritation from hydrogel, moisture, alcohol
Allergic contact dermatitis	Allergy to tape, hydrogel
Erosion	Mechanical trauma from shaving, array pressure/removal
Ulcer	Decreased perfusion from array pressure (especially in areas overlying scars, hardware, or prior radiation fields)
Skin infection/pustules	Secondary bacterial infection

## Preventive Strategies for Dermatologic Adverse Events

Category	Guidelines for Patient or Caregiver
Shaving and preparation of the scalp	Perform proper handwashing before preparation of the scalp for array application. Take time shaving the scalp, using gentle but firm circular motions. Ensure a close shave before applying the arrays. Cleaning the electric razor <i>after</i> every shave is important to lessen the risk of skin infection. Wash scalp with fragrance-free, mild shampoo (e.g., baby shampoo); seborrheic dermatitis shampoo may be used because it has antibacterial properties (e.g., pyrithione zinc 2%, ciclopirox 1%, ketoconazole 2%) Ensure that scalp is completely dry before applying a new set of arrays.
Use of 70% isopropyl alcohol	Use of first aid antiseptic rubbing alcohol before array application is a necessary step to remove naturally occurring scalp oils, resulting in better adherence of the arrays to the scalp. After shaving and before placing the arrays, wipe the scalp with a gauze or cotton ball soaked in the rubbing alcohol.
Transducer array exchanges	Avoid areas of skin irritation, because the rubbing alcohol may further irritate the skin. Change arrays on a regular basis (at least every 3-4 days). When removing the arrays, avoid "pulling" on the skin; take approximately 60 sec to remove each array. Use of mineral (baby) oil on the edges of the array may make removal of the adhesive tape easier and less irritating to the skin. To remove leftover array adhesive, use gauze or a cotton ball soaked in mineral (baby) oil or pour oil into hands and gently rub scalp in areas of remaining adhesive. Pay close attention to the scalp at each array exchange, and notify the doctor or nurse if there are signs of skin irritation or open areas, to receive information on how to treat them; taking a picture of the affected areas on the scalp and sharing it with the doctor or nurse is advised.

From Lacouture, M. E., Davis, M. E., Elzinga, G., Butowski, N., Tran, D., Villano, J. L., et al (2014). Characterization and management of dermatologic adverse events with the NovoTTF-100A System, a novel anti-mitotic electric field device for the treatment of recurrent glioblastoma. *Seminars in Oncology*, 41(Suppl 4), S1-S14.

Sample of a patient-specific adherence report. (© 2016 Novocure. All rights reserved.)

Specific treatments for dermatologic adverse events may include topical or oral antibiotics, topical corticosteroids (high potency as needed), and isolation of the affected skin areas from adhesives and pressure. If patients have intolerable grade 2 or 3 dermatologic adverse events, treatment should be interrupted and topical therapies applied. When the arrays are reapplied, they may be relocated (Lacouture et al., 2014). Other side effects reported by patients include headaches, weakness, falls, fatigue, and muscle twitching (Optune, 2014).

### Adherence

Patient adherence is recorded by the device onto internal log files. A patient-specific report is generated monthly and provided to the treating health care team (see figure on page 176) (Greifzu, Kuchinka, DiMeglio, Shackelford, & Benson, 2015). Patients may take short treatment breaks of 1 to 2 hours for personal care activities but are otherwise encouraged to continue normal activities of daily living while on therapy. Adherence can be maximized by having patients and caregivers adopt skin care strategies described in the previous section, minimizing the need for any treatment breaks. Use of properly ventilated hats and wigs may also improve adherence to TTFields therapy (Greifzu et al., 2015). Tightly woven wigs and hats made of material that traps heat can cause the device to alarm. The use of lighter materials, such as loosely woven wigs or ventilated wigs, permits heat to escape while providing a cosmetic effect.

### Ongoing Research with TTFields

A substantial body of evidence exists that supports the anticancer activity of TTFields across multiple cancer cell lines—including glioma, small cell lung cancer, breast cancer, melanoma, NSCLC, ovarian cancer, and pancreatic cancer—as well as in multiple animal tumor models and in patients with a variety of solid tumors. TTFields therapy has safely been combined with chemotherapy in clinical trials (Munster et al., 2015; Pless, Droege, von Moos, Salzberg, & Betticher, 2013).

### Additional Information

Optune is classified as durable medical equipment and it is approved for use within the home without continuous medical supervision. The therapy is covered by most major insurance carriers, either through published medical policy or on case-by-case review. Patient coinsurance varies by plan, and patients who cannot afford their coinsurance may be eligible for assistance from the manufacturer and third-party foundations. At completion of therapy, the device and system parts are returned to the manufacturer.

### Other Solid Tumors

TTFields are being studied at therapeutic intensities to treat solid tumors in the thorax (NSCLC, mesothelioma, squamous cell lung cancer), abdomen (pancreatic cancer), central nervous system (brain metastases from NSCLC), and pelvis (ovarian cancer). This novel treatment provides an opportunity for tumor response with potentially fewer side effects than with other treatments.

## CHAPTER 17

# Tumor-Treating Electric Fields for Glioblastoma

Kenneth D. Swanson, PhD<sup>a</sup>, Edwin Lok, MS<sup>a</sup>, Eric T. Wong, MD<sup>a,b,\*</sup>

### HISTORICAL CONTEXT OF ELECTRIC FIELD TREATMENT

The application of physical energy from various parts of the electromagnetic spectrum is common in glioblastoma treatment. The most widely used involves energies from the higher end of the spectrum in exahertz (the  $10^{18}$ -Hz range), in which ionizing radiation is used to treat various types of malignancies, including glioblastoma (Fig. 17.1). Therapeutic radiation can be diffuse, as in whole-brain and involved-field radiotherapy, or highly conformal, as in stereotactic radiosurgery (SRS), and the biological responses to these different types of radiation are different, as modeled by the linear-quadratic dose-effect relationship.<sup>1-3</sup> At the lower end of the spectrum, in the gigahertz or  $10^9$ -Hz microwave range, laser interstitial thermal therapy (LITT) is being used for the thermocoagulation of brain tumors and the treatment of radiation necrosis.<sup>4-6</sup> MRI technology now allows the real-time visualization of temperature changes during LITT treatment of a target lesion. In addition, at an even lower part of the electromagnetic spectrum, in the kilohertz or  $10^3$ -Hz range, alternating electric field therapy or tumor-treating electric fields (TTFields) are now an established treatment for glioblastoma.<sup>7</sup> This chapter provides a summary of the cell biology and physical science effects of TTFields on tumor cells and tumors in the brain, as well as a historical perspective of the clinical studies conducted in the glioblastoma population.

### BIOLOGICAL BASIS AND PHYSICAL SCIENCE SUPPORTING THE USE OF TUMOR-TREATING ELECTRIC FIELDS

#### Cell Biology Effects of Tumor-treating Fields

Early *in vitro* studies showed that cells exposed to TTFields underwent violent membrane blebbing during mitosis, thought to be a result of the disruption of alpha/beta tubulin assembly in mitotic spindles.<sup>8,9</sup> More detailed analysis revealed that these cells seem to transit normally through metaphase, showing normal rates of cyclin B destruction and metaphase exit at times consistent with the expected entry into anaphase.<sup>10</sup> However, anaphase and cytokinesis were perturbed, leading to aberrant mitotic exit. Mitosis is dominated by a myriad of processes that must be regulated spatially and temporally in order to ensure even distribution of parental genomic DNA into the resulting daughter cells. Most of the regulatory events during mitosis control functions that are involved in the migration and alignment of chromosomes, as well as the timing of the contraction of the cytokinetic furrow following chromosome separation. Given the timing of the TTField-induced cellular disruption during mitosis, they likely exert their effect on intracellular proteins that are necessary during late metaphase or anaphase and that bear high electric charges on which the TTFields can act. It is not clear whether these TTField effects are caused by their combined activities on multiple proteins or whether they arise from the perturbation of a single protein that serves a critical function. In order to serve as a TTField target,

**Fig. 17.1** Application of the electromagnetic spectrum in the treatment of brain tumors. Traditional ionizing radiation has a frequency in the exahertz, or  $10^{18}$  Hz, range, whereas laser-induced thermal therapy uses microwaves in the gigahertz, or  $10^9$  Hz, range to induce thermocoagulation. Tumor-treating electric fields use the lower end of the electromagnetic spectrum in the kilohertz, or  $10^3$  Hz, range. LITT, laser interstitial thermal therapy; TTFIELDS, tumor-treating fields. (Courtesy of Kisa Zhang, BS, Boston, MA.)

proteins must possess a sufficiently high dipole moment in order for the alternating electric fields generated by the TTFIELD therapy device to perturb its function in mitosis.

By examining the published dipole moment database of different proteins, the authors found that the heterotrimeric protein complex composed of septin 2, 6, and 7 possesses a dipole moment of 2711 Debyes (or  $10^{-18}$  statC·cm SI equivalent), which is 5 standard deviations greater than the median value derived from an analysis of more than 14,000 intracellular proteins.<sup>10,11</sup>

Importantly, this septin complex performs important functions during both metaphase and anaphase and its disruption by short hairpin RNA-mediated depletion resulted in blebbing during mitosis similar to that seen in TTFIELD-treated cells.<sup>12</sup> TTFIELDS are able to perturb normal septin localization during mitosis and cell spreading, which strongly suggests that TTFIELDS physically interact with this complex and exert their effects on mitotic cells by preventing the proper localization of this septin-containing complex to proper sites of action during mitosis (**Fig. 17.2**).

**Fig. 17.2** Interaction between TTFIELDS and tumor cells undergoing mitosis. TTFIELDS induce an electromechanical force on the septin 2, 6, and 7 complex that has an extremely large dipole moment of 2711 Debyes. This movement results in mitotic catastrophe and aberrant mitotic exit, leading to an increased cell surface expression of the endoplasmic reticulum chaperonin calreticulin and the secretion of HMGB1, which acts as a danger signal when released from cells, both of which are essential for immunogenic cell death.

The TTFIELD-induced catastrophe during anaphase results in a failure to complete division that results in a G<sub>0</sub>/G<sub>1</sub> arrest and p53-dependent apoptosis. Therefore, TTFIELDS are likely to exert an effect on multiple proteins and the resulting cumulative perturbation may be necessary to drive the observed mitotic catastrophe.

Postmitotic cells that are treated with TTFIELDS and aberrantly exit mitosis develop aneuploidy, and these aneuploid cells are in general resistant to apoptosis, a process that is known to trigger an immunosuppressive response in the host.<sup>13,14</sup> However, TTFIELDS also cause cytoplasmic stress and additional signs of immunogenic cell death, including high mobility group box 1 (HMGB1) secretion into the extracellular space, calreticulin upregulation on the cell surface, and annexin V binding.<sup>15,16</sup> These findings suggest that TTFIELDS may increase the immunogenicity of tumor cells *in vivo*. When highly metastatic VX-2 tumors were injected into the kidney capsules of rabbits and were treated with TTFIELDS for 7 days after their establishment, metastases to the lungs were markedly reduced compared with non-treated animals. Recovered lung metastases also revealed a significant increase in infiltration of immune cells within the tumors.<sup>17,18</sup> An interpretation of these results is that TTFIELDS acted to sensitize the animals against metastatic spread and that the increased leukocytic infiltrates reflected an increased requirement for the immunosuppressive stroma for their establishment and maintenance. As discussed later, patients treated with the immunosuppressive steroidal anti-inflammatory drug dexamethasone seem not to respond to TTFIELD treatments and those with higher levels of CD3<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> lymphocytes are more likely to have a better outcome on this therapy.<sup>19</sup> Collectively, these data strongly support an immunologic basis for the antitumor response from TTFIELD treatment.

### Physical Properties of Tumor-treating Fields and Electric Field Distribution Within the Brain

The physical effects of TTFIELDS are governed by the fundamental physics of Gauss' law, Ohm's law, the continuity equation, and Coulomb's law.<sup>20</sup> In addition, several factors, including a medium's electrical conductivity (a measure of the ability to pass charges) and relative permittivity (a measure of the ability to hold charges), can affect the electric field distribution within the brain tissue. Because each tissue type is unique, the intracranial structures must therefore be characterized based on their conductivity and permittivity values. The highly heterogeneous

consistency and geometry of the brain therefore distort the intracranial electric fields as induced by an external source. Electric fields are generally defined by instantaneous changes in electric potential. These changes in electric potential result in electromotive disruption of mitotic structures and are therefore the basis for the therapeutic benefit of TTFIELDS.<sup>9,10</sup> TTFIELD therapy for glioblastoma is delivered by 2 pairs of transducer arrays positioned orthogonally on the shaved scalp, adhered by a thin layer of conductive gel that provides good conductivity (Fig. 17.3).<sup>20,21</sup> TTFIELDS are generated by a battery-powered alternating current generator, operating at 200 kHz with maximum voltage alternating from +50 to -50 V.

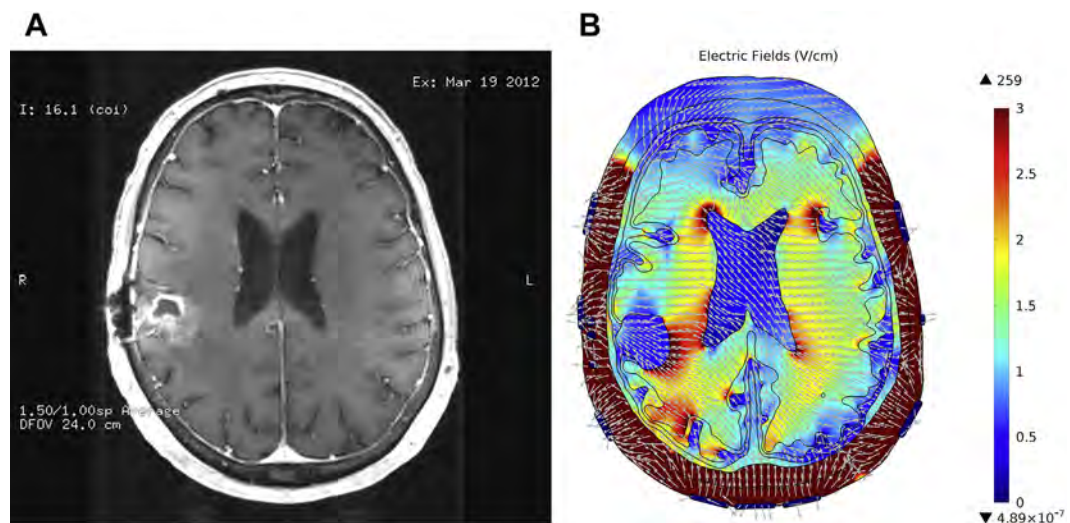

To obtain a comprehensive model of the electric field's distribution in the brain, computer modeling can be performed using coregistered patient DICOM (Digital Imaging and Communications in Medicine) data sets from T1-weighted postgadolinium, T2, and MPRAGE (Magnetization-Prepared Rapid Acquisition with Gradient Echo) MRI. Previously, Lok and colleagues<sup>22</sup> showed a heterogeneous distribution of electric fields in the brain, and the regions adjacent to the ventricular horns had a particularly high electric field intensity (Fig. 17.4). This high field intensity is likely caused by the higher electric conductivity of cerebrospinal fluid than the surrounding tissues, which behaves like the terminal of a capacitor, with the surrounding tissues functioning like a dielectric between conductive terminals. Since a dielectric medium generally retains charge, the rate at which the medium is able to collect and retain the charge is defined by its conductivity and relative permittivity. At 200 kHz, the effect of permittivity is overwhelmed by the conductivity of the medium (Fig. 17.5).<sup>23</sup> Furthermore, each medium has a unique capacitive reactance characteristic of the medium's conductivity, and the rate at which the medium is able to collect and retain charges is frequency dependent. At high frequencies, the medium only has limited time to collect a finite amount of charges and retain them before the field collapses as the polarity changes direction, thereby discharging the initially retained charges before repeating the process.

Because cerebrospinal fluid has a low permittivity value compared with its surrounding tissues, it is a poor dielectric medium and thus charges migrate through the fluid layer at a much faster rate with minimal charge retention. This property explains why most of the cerebrospinal fluid has very low electric field intensity. But this is not true at the interface between cerebrospinal fluid and its adjacent brain tissue. For a perfect solid

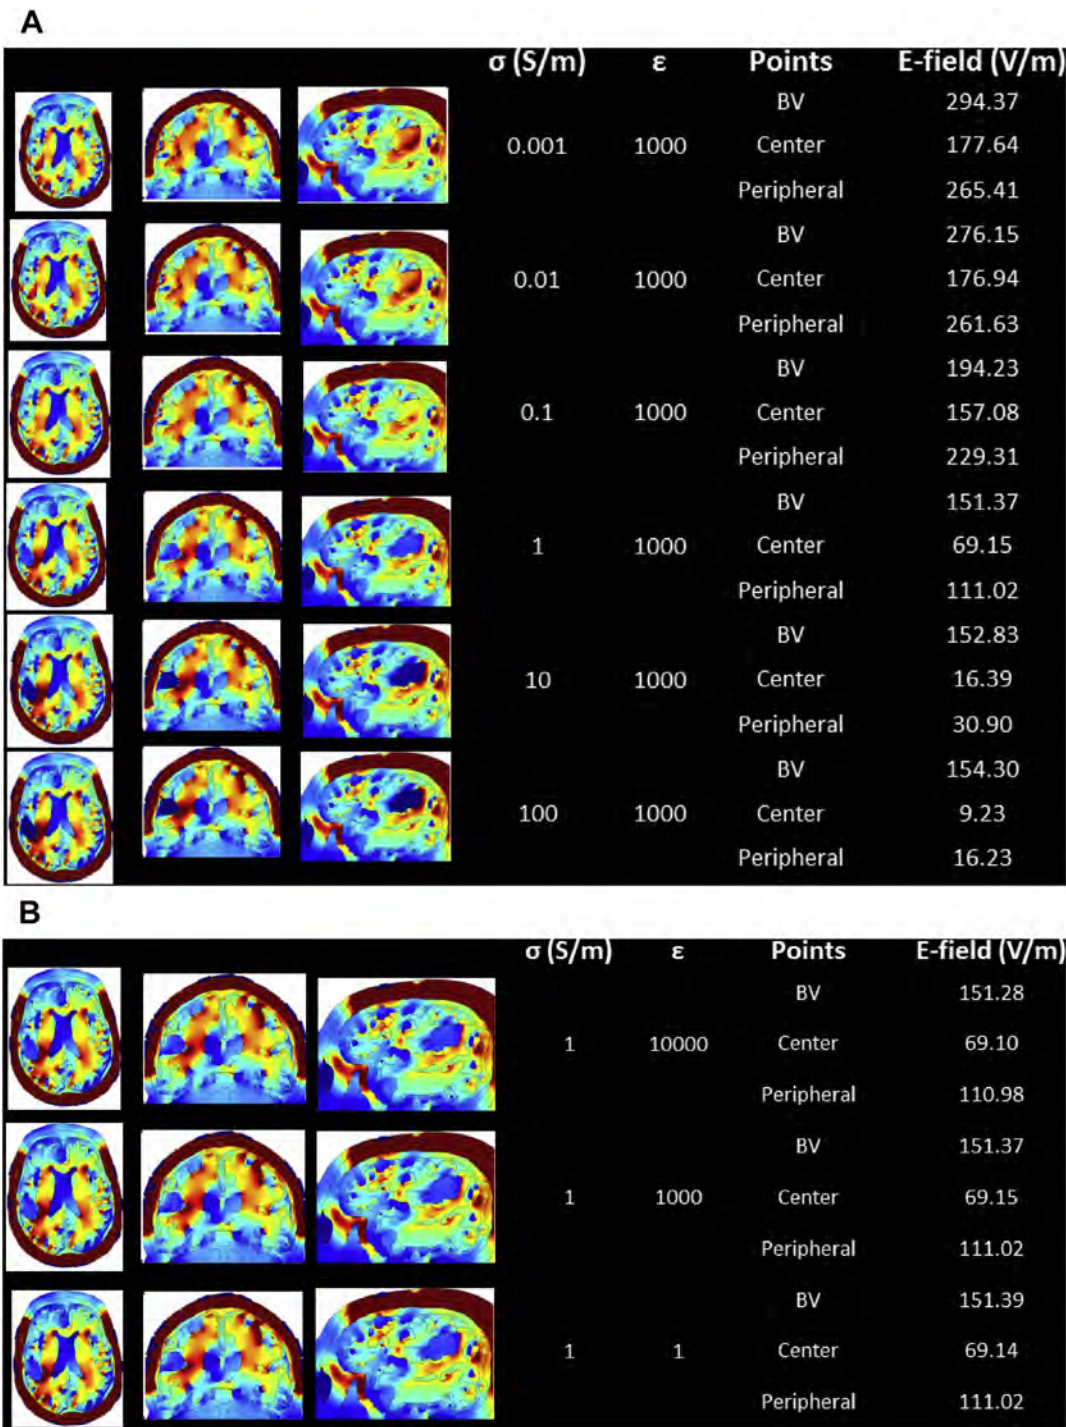

**Fig. 17.3** Transducer array placement for TTFields therapy. TTFields are delivered by 2 pairs of transducer arrays placed orthogonally (A–E) on the shaved scalp. The arrays are connected to a battery-operated current generator, operating at 200 kHz with peak-to-peak voltage from +50 to –50 V.

**Fig. 17.4** Intracranial distribution of TTFields. Computed modeling of a patient’s recurrent glioblastoma in the right parietal brain (A) revealed inhomogeneous electric field distribution within the intracranial space (B). High field strength was seen at the ventricular horns and the medial aspect of the tumor facing the lateral ventricle.

**Fig. 17.5** Sensitivity analysis of the electric field distribution in the gross tumor volume (GTV) as a function of conductivity or permittivity. (A) The electric field intensity of the GTV and the surrounding tissues decreased as the conductivity increased from 0.001 to 100 S/m. (B) However, the electric field intensity and distribution did not change significantly as permittivity varied from 1 to 10,000. BV, bilateral ventricles.

conductor, the electric field within it is zero, and the charges are uniformly distributed on the surface of the conductor. However, cerebrospinal fluid is neither a perfect conductor nor a dielectric.

When charges are positioned across a parallel flat surface, repulsive forces are generated and the charges dissipate away from each other. However, on surfaces with very steep geometric gradients

(ie, sharp corners), the repulsive forces are greatly increased because the charge density is much higher within a smaller surface area. Therefore, it is expected that the ventricular horns have a significantly higher electric field intensity than the rest of the cerebrospinal fluid space as a result of the bunching effect of charge distribution in a region with an irregularly sharp geometry.

The electric properties of gliomas can also vary among patients depending on their tumor composition. Tumors with larger necrotic cores are likely to have higher field intensities in the gross tumor volume because of the capacitive reactance, as explained earlier. In contrast, tumors with smaller or no necrotic core are likely to have lower field intensities at the center of the volume because of absence of an adjacent conductive medium to act as an electric current source. This property may become clinically relevant due to the increased requirement for time of exposure to TTFields as the outer layers of the gross tumor volume are treated by lower field intensities.

## EVIDENCE FOR THE USE OF TUMOR-TREATING ELECTRIC FIELDS IN THE TREATMENT OF RECURRENT AND DE NOVO GLIOBLASTOMAS

### First-in-Human Tumor-Treating Fields Therapy for Glioblastoma

The first-in-human pilot trial for safety and efficacy of TTFields therapy was conducted in Europe from 2004 to 2005 and enrolled 10 patients with recurrent glioblastoma.<sup>8</sup> The most common adverse event was contact dermatitis, which occurred in 9 patients and was thought to be a result of hydrogel-induced irritation on the scalp. Two patients experienced partial seizures that were related to their tumors. No toxicity on blood count or chemistry was seen, except for increased liver enzyme levels in those taking anticonvulsants. The median overall survival (mOS) of the 10 patients was 14.4 months. The time to tumor progression was 6.0 months and the 1-year overall survival (OS) rate was 67.5%, which compared favorably with the historical data of 5.8 months for mOS, 2.1 months for median progression-free survival (mPFS), and 21% for 1-year OS.<sup>8,24</sup> There was 1 complete and 1 partial responder who were alive at 84 and 87 months, respectively, from treatment initiation.<sup>25</sup> Importantly, the intensity of electric fields as directly measured in 1 patient was validated to be within 10% of the values estimated by computer modeling of the electric field distribution within the brain.<sup>8</sup>

A concurrent pilot study was conducted from 2005 to 2007 that enrolled 10 patients with newly

diagnosed glioblastoma.<sup>25</sup> TTFields were added to adjuvant temozolomide after initial standard-of-care radiotherapy and concomitant daily temozolomide.<sup>26</sup> The mPFS was 35.8 months and mOS was greater than 39 months, which compared favorably with the mPFS of 6.9 months and mOS of 14.6 months from the data in the phase III trial.<sup>25,26</sup> The only adverse event noted in the pilot cohort was scalp dermatitis, and that could be ameliorated by topical corticosteroids and periodic shifting of transducer arrays.<sup>25</sup> There were 2 long-term survivors who lived 84 and 64 months from their initial diagnoses.<sup>25</sup>

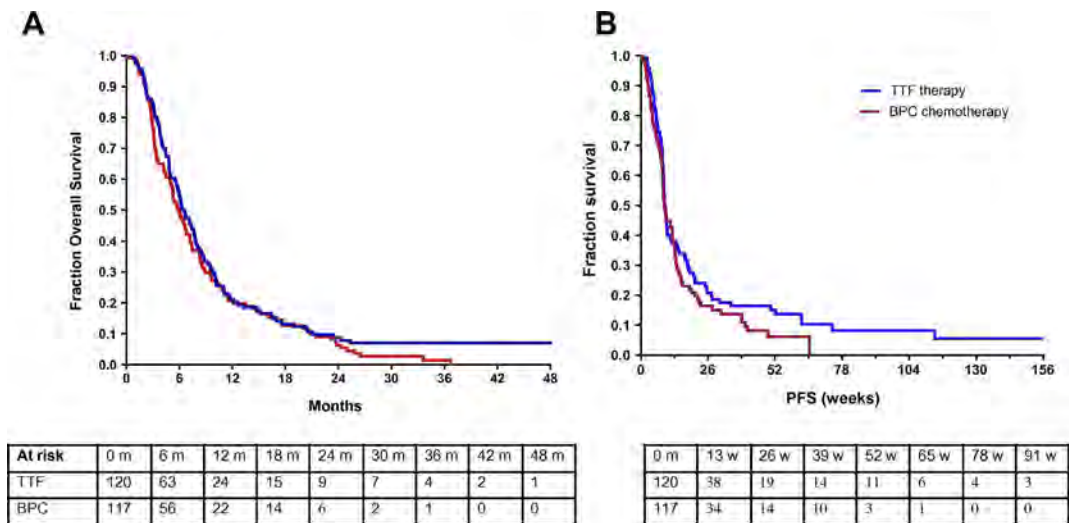

### Tumor-Treating Fields for Recurrent Glioblastoma

The phase III pivotal trial of TTFields for recurrent glioblastoma was conducted from 2006 to 2009 and the primary end point was OS (NCT00379470).<sup>27</sup> In the intent-to-treat population, the median OS was 6.6 months for subjects treated with TTFields versus 6.0 months for those who received best physician's choice (BPC) chemotherapy, with a hazard ratio of 0.86 ( $P = .27$ ) (Fig. 17.6). About 31% of the BPC chemotherapy cohort received bevacizumab alone or in combination with chemotherapy. The mPFS was 2.2 and 2.1 months respectively for TTFields and BPC chemotherapy treatment, with a hazard ratio of 0.81 ( $P = .16$ ). The progression-free survival (PFS) at 6 months was 21.4% and 15.1%, respectively ( $P = .13$ ). The 1-year survival rate was 20% in both cohorts. The outcome of the trial indicated that TTFields probably had efficacy comparable to chemotherapy and bevacizumab.

Grade 1 or 2 scalp irritations were the most common adverse events associated with the device. Shifting the arrays slightly during array exchange and applying topical corticosteroid can minimize this irritation.<sup>28</sup> There were far less hematological toxicity, appetite loss, constipation, diarrhea, fatigue, nausea, vomiting, and pain associated with the device when compared to BPC chemotherapy. Furthermore, analysis showed that device-treated patients had better cognitive and emotional functions. Based on the comparable efficacy results and absence of serious TTField-associated toxicities, the US Food and Drug Administration (FDA) approved TTFields therapy on April 8, 2011 for the treatment of recurrent glioblastoma.

The discrepancy in the OS rates between the results of the phase III trial and the robust outcome from the first-in-human pilot study prompted a series of *post hoc* analyses of the trial data. The first analysis centered on responders. This analysis showed that 5 of 14 responders treated with

**Fig. 17.6** Intent-to-treat Kaplan-Meier OS and PFS curves in the pivotal trial for patients with recurrent glioblastoma comparing TTField therapy with BPC chemotherapy. (A) The median OS was 6.6 months for patients treated with TTFields versus 6.0 months for those received BPC chemotherapy, with a hazard ratio of 0.86 ( $P = .27$ ). (B) The median PFS was 2.2 and 2.1 months respectively for TTFields and BPC chemotherapy treatment, with a hazard ratio of 0.81 ( $P = .16$ ). TTF, TTFields.

TTField monotherapy had prior low-grade histology, whereas none of the 7 responders treated with BPC chemotherapy did.<sup>29</sup> Second, the analysis revealed significantly less dexamethasone use in responders when compared to nonresponders.<sup>29</sup> Responders in the TTField monotherapy group received a median dexamethasone dose of 1.0 mg/d while nonresponders received 5.2 mg/d. A similar difference was also noted in the median cumulative dexamethasone dose of 7.1 mg for responders compared to 261.7 mg for nonresponders. In the chemotherapy cohort, the median dexamethasone dose used was 1.2 mg/d for responders while it was 6.0 mg/d for nonresponders. However, the median cumulative dexamethasone dose was not significantly different: 348.5 mg for responders versus 242.3 mg for nonresponders. These data suggest that TTFields efficacy may be influenced by concurrent dexamethasone use, which is a clinically modifiable factor. This finding prompted an in-depth analysis of the dexamethasone effect in the entire trial population.

Applying an unsupervised modified binary search algorithm that stratified the TTField monotherapy arm of the phase III trial based on the dexamethasone dosage that provided the greatest statistical difference in survival revealed that subjects who used greater than 4.1 mg/d of dexamethasone had a markedly shortened median OS of 4.8 months compared with those who received less than or equal to 4.1 mg/d, who had a median OS of 11.0 months (Fig. 17.7).<sup>19</sup> Subjects in the chemotherapy arm were observed to have a

similar, but less robust, dichotomization and those who used greater than 4.1 mg/d and less than or equal to 4.1 mg/d of dexamethasone had a median OS of 6.0 and 8.9 months, respectively. This difference in OS based on dexamethasone dose was unrelated to tumor size but was most likely caused by interference with patient immune effector function. A single-institution validation cohort of patients treated with TTField therapy, using their CD3<sup>+</sup>, CD4<sup>+</sup>, and CD8<sup>+</sup> T lymphocyte levels as a marker of immune competency, suggested the importance of immune competence to TTField therapy. Importantly, a dexamethasone dosage of greater than 4.0 mg/d was also a poor prognostic factor in newly diagnosed patients who completed radiotherapy,<sup>30</sup> supporting the conclusion that dexamethasone can interfere with treatment. With successive increases in dexamethasone dosage, both cohorts reached an inflection point near 8.0 mg/d, after which the rate of survival decreased slowly. Taken together, dexamethasone exerts a generalized and profound interference on the efficacy of both TTFields and chemotherapeutic treatment against glioblastoma. Therefore, dexamethasone use should be aggressively minimized.<sup>19,31</sup>

**Use of Tumor-Treating Fields Therapy in Clinical Practice**

The post-FDA-approval usage of TTField therapy in routine clinical practice may differ from that in the registration trial, primarily because clinical trial data may not always be representative of

**Fig. 17.7** Kaplan-Meier OS and tumor size with respect to dexamethasone requirement of less than or equal to 4.1 mg/d versus greater than 4.1 mg/d from subjects enrolled in the phase III trial comparing TTField therapy with BPC chemotherapy. (A) Subjects enrolled in the TTField treatment arm taking dexamethasone less than or equal to 4.1 mg/d (solid blue) versus greater than 4.1 mg/d (dashed blue), which was determined by an unsupervised binary partitioning algorithm. Subjects who used less than or equal to 4.1 mg/d of dexamethasone (n = 56) had a median OS of 11.0 months (95% confidence interval [CI], 8.8–16.6) compared with those who used greater than 4.1 mg/d (n = 64), who had a median OS of 4.8 months (95% CI, 3.9–6.0) ( $\chi^2 = 34.6$ ;  $P < .0001$ ). (B) Subjects enrolled in the BPC chemotherapy arm taking dexamethasone less than or equal to 4.1 mg/d (solid red) versus greater than 4.1 mg/d (dashed red), which was determined by the same unsupervised binary partitioning algorithm. Subjects who used less than or equal to 4.1 mg/d of dexamethasone (n = 63) had a median OS of 8.9 months (95% CI, 7.2–16.1) compared with those who used greater than 4.1 mg/d (n = 54), who had a median OS of 6.0 months (95% CI, 3.5–8.3;  $\chi^2 = 10.0$ ;  $P = .0015$ ). (C) Box-and-whisker plot of bidimensional tumor size in the TTField therapy cohort that received dexamethasone less than or equal to 4.1 mg/d versus greater than 4.1 mg/d. Subjects who took dexamethasone less than or equal to 4.1 mg/d (n = 56) had a median tumor size of 11.9 cm<sup>2</sup> (range, 0.0–56.7 cm<sup>2</sup>) compared with those who used greater than 4.1 mg/d (n = 64), who had a

treatment outcome in routine clinical practice environments. Reasons for this discrepancy may arise from the prespecified clinical characteristics that trial subjects must possess that real-world patients may not have. As a result, trial subjects typically have healthier neurologic functions, better performance status, and fewer medical comorbidities, all of which may enable trial subjects to benefit more from the new treatment. Furthermore, the FDA must strike a fine balance between providing the public rapid access to new treatments for deadly diseases and requiring comprehensive data and protracted reviews on their benefits and risks. This action sometimes results in the reversal of prior accelerated approval decisions. Therefore, these issues prompted the development of the Patient Registry Data Set (PRiDe) to capture data on TTField usage among patients in the routine clinical practice environment.

PRiDe consisted of 457 patients from 91 treatment centers in the United States. Patients treated in PRiDe had a median OS of 9.6 months compared with 6.6 months in the TTField monotherapy arm in the registration trial.<sup>27,32</sup> The 1-year OS rate was also longer at 44% compared with 20%, respectively.<sup>27,32</sup> The difference in survival characteristics is most likely caused by the higher proportion of patients treated with TTFields at first recurrence in PRiDe (33%) than in the registration trial (9%). Treatment at an earlier timepoint in the disease process may provide a higher efficacy than treatment at a later timepoint. Absence of prior bevacizumab usage was also favorable.<sup>32</sup> Nevertheless, the heterogeneity in the adjunctive treatments used in conjunction with TTField therapy in PRiDe that was not adequately captured, which included cytotoxic chemotherapy, bevacizumab, or even alternative medicine, is an important caveat that makes it statistically noncomparative with the TTField monotherapy arm in the phase III trial.

### Efficacy of Tumor-Treating Fields Therapy for Newly Diagnosed Glioblastoma

A phase III randomized open-label study of TTField therapy was conducted in 700 patients with newly diagnosed glioblastoma between 2009 and 2014 (NCT00916409). After their initial

radiotherapy and concomitant daily temozolomide, subjects were randomized in a 2:1 fashion to receive either TTFields plus maintenance temozolomide or maintenance temozolomide alone.<sup>33</sup> The primary end point was PFS. In a prespecified interim analysis of the first 315 subjects after a minimum follow-up of 18 months, the intent-to-treat cohort that received TTFields plus temozolomide had a longer PFS than the cohort treated with temozolomide alone: median 7.1 versus 4.0 months (hazard ratio = 0.62; 95% confidence interval [CI], 0.43–0.89; log rank  $P = .0014$ ) (Fig. 17.8). The median OS also favors the TTFields plus temozolomide group, at 19.6 versus 16.6 months respectively (hazard ratio = 0.74; 95% CI, 0.56–0.98; log rank  $P = .034$ ), as well as the per protocol population that completed more than 1 cycle of treatment, at 20.5 versus 15.6 months respectively (hazard ratio = 0.64; 95% CI, 0.42–0.98; log rank  $P = .004$ ).

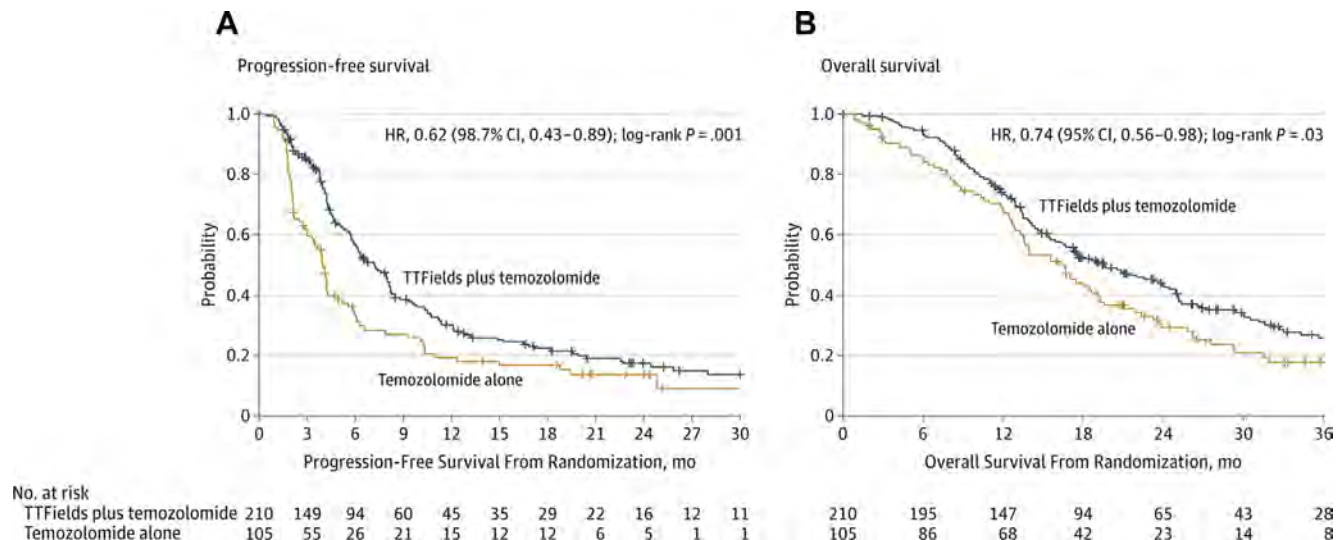

The trial population experienced no unexpected adverse events.<sup>33</sup> Grade 3 and 4 hematological toxicities between the TTFields plus temozolomide and temozolomide alone cohorts (12% vs 9%), gastrointestinal disorders (5% vs 2%), and convulsions (7% vs 7%) were not significantly different. Only scalp reaction was more commonly seen in those who received TTFields plus temozolomide. Based on the favorable efficacy and toxicity data, the US FDA granted approval on October 5, 2015 to use TTFields in conjunction with maintenance temozolomide in the adjuvant setting for patients with newly diagnosed glioblastoma.

### SUMMARY

Human clinical trial testing of TTField efficacy was started in neuro-oncology, initially for the treatment of recurrent glioblastoma (NCT00379470) and later in newly diagnosed glioblastoma (NCT00916409).<sup>27,33</sup> This route of development for a new anticancer therapy is highly unusual because treatments in neuro-oncology were traditionally adopted from established therapies from other disease sites, when the accompanying preclinical scientific data on the mechanisms of action had been firmly established. Nevertheless, the 2 pivotal trials conducted in glioblastoma have

median tumor size of 16.8 cm<sup>2</sup> (range, 0.3–51.0 cm<sup>2</sup>). ( $P = .1369$ ). (D) Box-and-whisker plot of bidimensional tumor size in the BPC chemotherapy cohort that received dexamethasone less than or equal to 4.1 mg/d versus greater than 4.1 mg/d. Subjects who took dexamethasone less than or equal to 4.1 mg/d ( $n = 63$ ) had a median tumor size of 4.2 cm<sup>2</sup> (range, 0.0–11.2 cm<sup>2</sup>) compared with those who used greater than 4.1 mg/d ( $n = 54$ ), who had a median tumor size of 9.6 cm<sup>2</sup> (range, 0.0–46.0 cm<sup>2</sup>) ( $P = .1638$ ).

**Fig. 17.8** Prespecified interim analysis of PFS and OS in registration trial for patients with newly diagnosed glioblastoma comparing maintenance TTField therapy plus temozolomide versus temozolomide alone. Kaplan-Meier comparison of the two cohorts showed (A) a median PFS of 7.1 versus 4.0 months respectively, with a hazard ratio of 0.62 ( $P = .0014$ ), and (B) a median OS of 19.6 versus 16.6 months respectively, with a hazard ratio of 0.74 ( $P = .034$ ).

helped to established TTFields as a *bona fide* anti-cancer treatment and its efficacy is being actively investigated in glioblastoma as well as other malignancies both within and outside the central nervous system.

To improve the efficacy of TTFields treatment of recurrent glioblastomas, there is a strong rationale for combining it with SRS. Large-fraction radiotherapy might potentiate immune-mediated antitumor activity.<sup>34,35</sup> The addition of TTFields after SRS may further potentiate this effect because exposed tumor cells show cell surface expression of calreticulin and secretion of HMGB1, both of which are required to generate immunogenic cell death.<sup>15,36,37</sup> Furthermore, a *post hoc* analysis of the phase III trial for recurrent glioblastoma showed that the application of TTFields among subjects who had progressed on bevacizumab ( $n = 23$ ) resulted in a longer mOS of 6.0 months compared with a mOS of 3.3 months ( $n = 21$ ) in those treated with BPC chemotherapy (hazard ratio = 0.43; 95% CI, 0.22–0.85;  $\chi^2 P = .06$ ).<sup>38</sup> In addition, the favorable intracranial safety profile of TTFields and bevacizumab suggests that the combination will most likely have an acceptable level of toxicity.<sup>38,39</sup> There is a planned Radiation Therapy Oncology Group foundation study on TTFields and bevacizumab in patients with recurrent glioblastoma who have progressed while on bevacizumab.

Several investigator-initiated combination trials are being conducted using (1) TTFields in combination with bevacizumab and carmustine in patients with glioblastoma at first relapse (NCT02348255), (2) TTFields with bevacizumab and hypofractionated stereotactic radiotherapy for bevacizumab-naïve patients with recurrent glioblastoma (NCT01925573), and (3) TTFields in combination with temozolomide and bevacizumab for patients with newly diagnosed glioblastoma in the maintenance phase of treatment, after initial radiotherapy with concomitant temozolomide and bevacizumab (NCT02343549). In addition, a study has been designed to find genomic signatures of recurrent glioblastoma that may correlate with response to TTFields (NCT0194576). Collectively, these planned and ongoing studies indicate the current state of interest in combining TTFields with other established modalities of treatment for glioblastoma.

# High-Grade Gliomas

Andrew B. Lassman, Diana Matcayevsky,  
and Benjamin W. Corn

## INCIDENCE

There are approximately 68,000 new cases of brain tumors diagnosed in the United States each year. Gliomas now account for nearly 80% of malignant brain tumors. Glioblastoma (GBM) is the most common primary malignant brain tumor.<sup>1</sup>

## BIOLOGIC CHARACTERISTICS

A better prognosis is associated with grade III tumors (as classified by the World Health Organization [WHO]) when compared with grade IV tumors (i.e., GBM) and for oligodendrogliomas when compared with astrocytomas. A better response to therapy and higher rates of survival are associated with oligodendroglial tumors manifesting 1p19q codeletions and IDH mutations. Methylation of the promoter for the *MGMT* gene predicts for increased sensitivity to DNA alkylating agents such as temozolomide and is prognostic for overall survival (OS) in patients with GBM, especially older patients.

## STAGING EVALUATION

Optimal imaging is carried out with contrast-enhanced magnetic resonance imaging (MRI). Computed tomography (CT) scans are primarily used as an infrastructure for radiation treatment planning before fusion with MRI images. On the first postoperative day, an MRI study should be obtained to evaluate the extent of resection and as a basis for radiation treatment planning.

## PRIMARY THERAPY AND RESULTS

The standard of care for the definitive treatment of newly diagnosed GBM in patients aged 18 years to 70 years is the delivery of approximately 60 Gy of fractionated partial brain radiotherapy following maximal safe surgical debulking. Irradiation (most commonly administered with conformal strategies) should be accompanied by concurrent temozolomide chemotherapy. Adjuvant temozolomide is also administered for at least 6 months following the end of radiotherapy unless disease progression occurs.

Temozolomide has not been established as a component of standard therapy for newly diagnosed WHO grade III gliomas; ongoing trials are investigating this issue.

Prospective randomized trials could not define a role for either brachytherapy or radiosurgery in the initial management of high-grade gliomas.

## LOCALLY ADVANCED DISEASE AND RECURRENCE

Bevacizumab has been approved for salvage of failures following definitive therapy for GBM. If chemotherapeutic options are not available in the setting of recurrence, creative radiotherapeutic strategies (e.g., radiosurgery, intensity-modulated radiation therapy [IMRT], brachytherapy) may be considered.

High-grade gliomas are almost universally fatal. Although recently discovered combined-modality approaches have prolonged survival, many patients succumb relatively quickly, and cure remains elusive for the majority.

New protocols have recently emerged after decades of limited progress in the management of these tumors. New chemotherapeutic drugs, such as temozolomide, have found application in GBM. Bevacizumab is effective in recurrent disease and prolongs radiographic disease control in first-line regimens. In the future, molecular profiling may also allow tailoring of specific treatment to the patients most likely to benefit.

## ETIOLOGY AND EPIDEMIOLOGY

Most malignant brain tumors are high-grade gliomas, and most of these are GBM, a WHO grade IV tumor. The remainder are WHO grade III tumors such as anaplastic astrocytoma, anaplastic oligodendroglioma, and anaplastic oligoastrocytoma. Men are more commonly affected than women. The peak incidence occurs in the age range of 65 years to 75 years, and the median survival time is inversely proportional to age; these findings have prompted a redoubling of efforts in elderly subpopulations.<sup>1</sup>

There has been concern for cancer development following exposure to electromagnetic fields, but definitive evidence is lacking. More recently, the use of cellular telephones has been studied extensively in Europe,<sup>2</sup> but its importance as a risk factor has not been established. In terms of chemical exposure, nitrosamines have long been regarded as culpable, but causality is far from proven.<sup>3</sup> Brain tumors have also been linked with previous exposure to therapeutic ionizing radiation.<sup>3</sup> However, the absolute risk is low.

Most gliomas are sporadic, but genetic susceptibility is suspected based on the occurrence of multiple brain tumors in families with germline mutation of the *TP53* suppressor gene and patients with neurofibromatosis type I as well as the rare patients who have been diagnosed with Turcot's syndrome. A heritable syndrome contributes to less than 5% of GBMs.<sup>4</sup>

## PREVENTION AND EARLY DETECTION

No viable strategy for screening or early detection of glial tumors has been developed. There is also no convincing evidence demonstrating either improved survival when high-grade gliomas are found early, or a clear rationale for prophylactic strategies to reduce the incidence of these aggressive tumors.<sup>3</sup>

## BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Investigators around the world are searching for the molecular biologic characteristics of gliomas in an effort to improve therapy. For example, work by the Cancer Genome Atlas Research Network<sup>5</sup> and others<sup>6,7</sup> suggests that at least three molecular subclasses of GBM exist with potential therapeutic and prognostic implications. Mouse modeling has also demonstrated the oncogenic importance of abnormalities in receptor signaling (e.g., epidermal growth factor receptor [EGFR] and platelet-derived growth factor receptor [PDGFR]), signal transduction cascades (e.g., RAS and AKT), and cell cycle regulation.<sup>8</sup>

In the early 1990s, it was recognized that deletion of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q) occurs in most oligodendrogliomas.<sup>9</sup> Codeletion of 1p and 19q is prognostic for longer survival,<sup>10-12</sup> although until recently controversy existed as to whether this finding should alter therapy.<sup>13</sup> It is now recognized that an unbalanced chromosomal translocation underlies 1p/19q codeletion,<sup>14,15</sup> but the specific genes involved and their mechanism of action remain elusive. More recently, mutations in the isocitrate dehydrogenase 1 and 2 (*IDH1* and *IDH2*) genes, occurring most often in low-grade gliomas but also in a minority of WHO grades III and IV tumors have been described,<sup>16,17</sup> and are prognostic for longer survival.<sup>12,16,18,19</sup> Methylation of the *MGMT* promoter (see the section on [chemotherapy](#)) is emerging as a potential but imperfect predictive and prognostic factor in the treatment of newly diagnosed GBMs.

With the exception of 1p19q codeletion in anaplastic tumors, it is not yet clear how to best incorporate molecular data into the treatment of individual patients. Detailed discussions of the biologic characteristics of glioma and their clinical relevance are beyond the scope of this chapter and can be found elsewhere.<sup>20</sup>

## PATHOLOGY AND PATHWAYS OF SPREAD

The WHO classification system<sup>21</sup> is derived in part from the correlation between pathologic findings and survival rates observed by Bailey and Cushing<sup>22</sup> and published in the early 1900s. In current parlance, *low grade* refers to WHO grades I to II tumors and *high grade* to WHO grades III to IV tumors (Figure 27-1). However, the WHO grade I gliomas (e.g., juvenile pilocytic astrocytomas) are biologically different tumors from the others, infrequently occur in adults, and may be amenable to surgical cure. *Anaplastic* in the context of gliomas refers to WHO grade III tumors such as anaplastic astrocytomas, anaplastic oligodendrogliomas, and anaplastic oligoastrocytomas. GBM is a WHO grade IV astrocytoma, although the most recent WHO classification scheme does account for other rare subtypes, including GBM with oligodendroglial components.

WHO grades II to IV gliomas are characterized by a tendency to directly infiltrate adjacent brain tissue. Lesions with direct access to the corpus callosum may extend across the midline and configure themselves in a classic “butterfly pattern” (Figure 27-2). MRI underestimates the extent of invasive disease, and the diffusely infiltrative nature of these tumors makes complete removal of all tumor cells impossible. This “misleading appearance of enucleability” was described more than 80 years ago.<sup>22</sup> Leptomeningeal spread occurs occasionally (Figure 27-3). Hematogenous and lymphatic spread are exceedingly uncommon.<sup>23</sup>

**Figure 27-1** Highly cellular astrocytic glioma with foci of microvascular proliferation (asterisk) and pseudopalisading necrosis (diamond) consistent with glioblastoma.

**Figure 27-2** “Butterfly” glioblastoma (long arrow); a separate satellite lesion in the right parietal lobe (short arrow) is also apparent. The contrast enhancement with central necrosis is classic for a glioblastoma, which was histologically confirmed by biopsy.

## CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

No specific symptom constellation is pathognomonic of high-grade glioma. Typically, patients present with some combination of headaches, neurologic deficits, nausea, and vomiting, depending on tumor size and location. It is not unusual for patients to present with or subsequently develop seizures. Tissue for pathologic diagnosis can be obtained via stereotactic biopsy, open biopsy, or gross resection in the context of craniotomy. More complete resection improves diagnostic accuracy, provides additional tissue for molecular analyses, and is increasingly thought to improve OS.

The typical imaging appearance of a GBM is a ring-enhancing or heterogeneously enhancing lesion. The differential diagnosis may include stroke, brain metastasis, primary central nervous system lymphoma, demyelination, and even infectious or other inflammatory diseases. If a brain metastasis

is suspected, it is prudent to perform an appropriate extracranial evaluation to identify the primary malignant tumor. If there is a high index of suspicion for primary central nervous system lymphoma, such as in multifocal, periventricular, or homogeneously enhancing lesions,<sup>24</sup> corticosteroids should be withheld preoperatively unless herniation is imminent because their use may confound the histologic diagnosis.

Nearly all GBMs demonstrate contrast enhancement. However, up to 10% of anaplastic gliomas will not manifest such a pattern on imaging. Background uptake in the brain (an organ with an inherent avidity for glucose) significantly compromises the use of glucose-based positron emission tomography (PET) as a diagnostic tool for high-grade gliomas.

An algorithm for the evaluation and management of patients with GBM is shown in Figure 27-4.

## PRIMARY THERAPY

### Prognostic and Predictive Factors

Historically, all high-grade gliomas were lumped together in most clinical trials, thereby confounding results because of maldistribution of patients with differing prognoses. In 1993, Curran et al<sup>25</sup> published a landmark paper describing a prognostic classification scheme based on clinical variables. Data from three Radiation Therapy Oncology Group (RTOG) trials that enrolled nearly 1600 patients with high-grade glioma from 1974 to 1989 were used. This recursive partitioning analysis (RPA) methodology builds decision trees to model predictors by examining all possible “cut points” for all variables included in the model. Patients were segmented into six distinct groups with different survival outcomes. The key variables included patient age, performance status, histologic tumor type (i.e., anaplastic astrocytoma versus GBM), mental status, symptom duration antecedent to diagnosis, extent of resection, neurologic function, and radiotherapy dose. Median survival ranged from 4.6 months for class VI patients to almost 5 years for class I patients, underscoring heterogeneity. The European Organization for Research and Treatment of Cancer (EORTC) demonstrated that the prior RTOG RPA classification remained valid among patients in a more recent Phase III trial.<sup>26</sup> An RPA for anaplastic oligodendroglial tumors has also been proposed.<sup>27</sup>

One of the more controversial factors in the setting of high-grade gliomas has been the extent of surgical resection. Bailey and Cushing observed longer survival following resection in their 1926 publication,<sup>22</sup> as did others in the 1960s.<sup>28</sup> Numerous series since then also support more complete resection as a prognostic factor.<sup>29-33</sup> One of the largest involved more than 400 patients at the M. D. Anderson Cancer Center and demonstrated improved median survival (13 versus 8.8 months;  $p < 0.0001$ ) following at least 98% resection, as defined by postoperative MRI scans.<sup>34</sup> One small randomized study of 30 patients older than 65 years demonstrated improved survival rates following resection versus biopsy alone.<sup>32</sup> Use of 5-aminolevulinic acid fluorescence intraoperatively improves the likelihood of gross total resection,<sup>29</sup> but the effect on survival is debated.

## Surgery

Patients can often undergo a craniotomy where the goal is the safe removal of the largest possible volume of tumor to establish a diagnosis and relieve mass effect. High-grade gliomas are not surgically curable because of their extensive infiltration.

If biopsy rather than resection is pursued, choices include stereotactic options with CT or MRI guidance or open craniotomy and biopsy. Some have employed metabolic imaging such as magnetic resonance spectroscopy (MRS) to better select the biopsy sites most likely to contain the most aggressive portions of the tumor, but this is not widely used. Usually, stereotactic biopsy can be performed using either frame-based or frameless neuronavigation systems. The pathologist can review the frozen section to make an immediate preliminary diagnosis and confirm tissue adequacy.

When craniotomy is contemplated, meticulous planning is invested in the scalp incision and flap design. Special care must be taken to preserve the vascular supply of the scalp. The bony opening is devised to be sufficiently large to facilitate resection without needlessly exposing adjacent brain to the risk of injury. After opening the scalp, burr holes are placed and connected with a craniotomy. The bone flap is removed and the dura mater is opened. As a rule, the bone flap is reattached at the end of the resection, although some surgeons prefer not to reattach the bone flap.

Although tumors on the brain surface are immediately visible after exposure, subcortical lesions are harder to discern. Frameless image-guided neuronavigation systems are employed to localize subcortical tumors along with intraoperative ultrasound and MRI. Tumors that are situated near “eloquent” areas of cortex, such as those harboring motor and speech function, are mapped intraoperatively via electrical cortical stimulation to achieve maximal tumor debulking without operative morbidity. Resection of gliomas in the dominant hemisphere is often carried out under local anesthesia with supplementary sedation to allow speech mapping.

Occasionally, tumors may be removed en bloc via circumferential dissection, but more frequently, resection is effected in piecemeal fashion. A cavitation ultrasonic surgical aspirator (CUSA) facilitates removal of a firm, adherent, or calcified tumor.

Patients are routinely monitored in an intensive care unit following a craniotomy. The first MRI is obtained within 24 hours to 48 hours after surgery before postoperative changes set in. The extent of resection can be determined in this manner.

## External Beam Irradiation

External beam irradiation (EBRT) has historically been the cornerstone of the therapeutic approach to GBM (and anaplastic astrocytoma) for the past half-century, and its use in brain tumors was already described by the 1920s.<sup>35</sup> In the 1970s and early 1980s, categorical level I data became available from several studies,<sup>36</sup> including prospective Phase III trials conducted by the Brain Tumor Study Group (BTSG)<sup>37,38</sup> (Table 27-1).

The radiotherapeutic approach to high-grade glioma has evolved. Initially, large opposed lateral fields were employed to cover the entire brain volume. In 1989, Shapiro et al<sup>42</sup> published data from Brain Tumor Cooperative Group trial 80-01, in which the randomization was altered during the trial to compare partial brain irradiation with whole-brain radiotherapy (WBRT). No difference in OS or change in the patterns of failure was seen. Accordingly, WBRT is generally not advocated, except perhaps in the scenario of a widespread intracranial process such as gliomatosis cerebri.<sup>43</sup>

Several lines of evidence have influenced the trend to treat the gross tumor volume along with a margin of approximately 2 cm. In a classic paper published in 1980, Hochberg and Pruitt<sup>44</sup> used CT scans to determine that nearly 90% of GBM recurrences occurred within 2 cm of the primary tumor site (although this may be changing with the use of bevacizumab). Wallner et al<sup>45</sup> assessed the patterns of recurrence in 32 patients with unifocal malignant gliomas who were treated with primary surgery and postoperative irradiation. Nearly 80% of patients manifested recurrence or progression within 2 cm of the original tumor. Even when 80 Gy of partial brain irradiation was used in a prospective Phase I trial,<sup>46</sup> 90% of patients failed within the high-dose region.

It has been demonstrated on biopsy and autopsy studies that the abnormality detected on T2 or fluid-attenuated inversion-recovery (FLAIR) images harbors microscopic tumor extension. Accordingly, 45 Gy to 50 Gy is generally delivered, in 1.8-Gy to 2-Gy fractions, to the T2/FLAIR abnormality seen

\*p = 0.001 for radiation therapy versus observation/supportive care and radiation therapy plus carmustine versus observation/supportive care.

†p ≤ 0.003 for radiation therapy, radiation therapy plus carmustine, and radiation therapy plus semustine versus semustine alone.

‡p < 0.0001. Most patients randomized to radiation therapy alone crossed over to temozolomide at time of relapse or progression.

on the image, followed by a boost to raise the total dose to 60 Gy based on the T1-enhancing abnormality. The MRI abnormalities, however, remain quite nonspecific in terms of histopathologic confirmation, and even when novel strategies such as MRS are used for radiotherapy planning, there can be over or underestimation of the true extent of microscopic spread.<sup>47</sup>

A novel view of target definition has recently been proposed.<sup>48,49</sup> This approach posits that neuroprogenitor cells in the subventricular zone (SVZ) play a role in tumor recurrence. In retrospective analyses of dose distribution among patients with GBM, investigators found that the deposition of high dose (e.g., >40 Gy) in the ipsilateral SVZ was associated with a significantly improved progression-free survival (PFS) and OS in patients who also achieved gross total resection of their tumors. To validate this hypothesis, prospective clinical trials will need to be conducted to determine if cancer stem cells will need to be encompassed when delineating the targets for irradiation of high-grade glioma.

### Rationale for Current Total Irradiation Dose

A pooled analysis of three successive randomized trials conducted by the Brain Tumor Study Group (BTSG 66-01, 69-01, 72-01, respectively) generated data to support doses in excess of 50 Gy.<sup>50</sup> A stepwise improvement in survival was observed with doses ranging from less than 45 Gy to 60 Gy, consistent with dose response. A comparison of 70 Gy versus 60 Gy demonstrated no survival or local control advantage for the 70-Gy dose.<sup>51,52</sup> These results established 60 Gy as the standard of care.

Dose escalation has remained an important investigational option because there is still a pattern of failure characterized by local progression or recurrence. There are now multiple techniques for dose escalation, including three-dimensional conformal irradiation, radiosurgery, and brachytherapy, but these have not yielded higher rates of disease control or survival. Increasing the radiotherapy dose or reirradiation with radioprotective or antiangiogenic agents may be a useful strategy in the future.<sup>53</sup>

### Altered Fractionation

The RTOG has systematically and rigorously studied hyperfractionation for high-grade gliomas. In RTOG 83-02, patients were randomized to one of four dose arms (64.8 Gy, 72 Gy, 76.8 Gy, or 81.6 Gy) using twice-daily fractions of 1.2 Gy. Initial results suggested the superiority of 72 Gy,<sup>54</sup> but a subsequent Phase III trial demonstrated no improvement.<sup>55</sup> Prados et al<sup>56</sup> used an elegant randomization to assess not only a hyperfractionation schedule, but also to determine the activity of difluoromethylornithine (DFMO), a compound that inhibits sublethal and potentially lethal damage repair. Unfortunately, neither intervention improved survival.

### Stereotactic Irradiation

Two provocative small-scale experiences prompted the design of Phase III trials to formally evaluate radiosurgery for high-grade gliomas.<sup>57,58</sup> Loeffler et al<sup>57</sup> reported on 37 patients treated with 59.4-Gy fractionated radiotherapy followed by a stereotactic radiosurgery (SRS) boost to a median dose of 12 Gy. After a median follow-up period of 19 months, a 76% survival rate was reported. Sarkaria et al<sup>58</sup> described 115 patients with high-grade glioma who received conformal radiation therapy and a SRS boost; median survival time was 96 weeks. These results called into question whether they represented a benefit from SRS or simply selection bias.

RTOG 93-05 compared conformal irradiation plus carmustine with or without a SRS boost for newly diagnosed GBM. No differences were observed in terms of OS (median, approximately 13 months in each arm) or quality of life.<sup>59</sup>

SRS may still have a role in the treatment of recurrent disease, particularly if a focal region of recurrence can be defined.<sup>63</sup> However, this has not been tested in prospective trials.

### Brachytherapy

Brachytherapy, the use of implanted radioactive material at the site of the tumor offers a mechanism for focal dose escalation. Both permanent and temporary radioactive implants have been used. Early positive results by Gutin et al<sup>60</sup> suggested a potential survival benefit in a Phase II trial. These findings were not reproduced in subsequent randomized trials.<sup>61,62</sup>

Interest in this modality was rekindled when the GliaSite radiation therapy system (Proxima Therapeutics, Alpharetta, Georgia) received approval by the Food and Drug Administration (FDA) in 2001. This intracavitary device is implanted at the time of tumor debulking, and a solution of iodine-125 (<sup>125</sup>I) is injected into an expandable closed-catheter balloon. A retrospective study suggested reasonable safety and promising efficacy.<sup>63</sup> A Phase I study was conducted.<sup>64</sup> However, the implant induces changes in imaging that complicate determination of disease progression.<sup>65</sup>

### Chemotherapy: Concurrent with EBRT, Maintenance, and Other

Early randomized trials of chemotherapy were individually negative, but meta-analysis of these trials showed that 15% to 20% of patients treated with radiation therapy (RT) and nitrosoureas survived at least 18 months versus 5% treated with radiotherapy alone (Table 27-1).<sup>37,38,66,67</sup> Nitrosoureas, especially carmustine, were the most commonly used drugs, although procarbazine was also used extensively.<sup>68</sup> The combination of procarbazine, lomustine (CCNU), and vincristine (PCV)<sup>69</sup> had no clear benefit (yet much greater toxicity) versus carmustine for anaplastic astrocytoma,<sup>70</sup> and this regimen has been largely abandoned for nonoligodendroglial tumors.

Intratumoral delivery of chemotherapy for residual postoperative disease is most commonly in the form of carmustine-eluting (Gliadel) wafers. Patients undergoing wafer implantation during surgery for recurrent GBM survived approximately 2 months longer than patients without wafers in one study ( $p = 0.02$ ).<sup>71</sup> Treatment of newly diagnosed disease also yielded a 2-month prolongation of average survival.<sup>72,73</sup> However, this was not statistically significant when the analysis was restricted to patients with GBM histology. Of note, wafer delivery of carmustine versus systemic administration has not been compared for safety or efficacy. Gliadel does, however, carry an FDA label for implantation during resection of recurrent GBM and newly diagnosed malignant glioma. Attempts to treat residual visible or microscopic disease with other local chemotherapies delivered through implanted catheters and using convection-enhanced migration of drug have generally failed.<sup>74</sup>

Currently, the most widely used chemotherapeutic agent is temozolomide. Whether it is more effective than nitrosoureas has not been investigated, but it is unquestionably better tolerated with significant myelosuppression in less than 20% of patients.<sup>39,40</sup> Temozolomide was first approved for use in the United States in recurrent anaplastic astrocytomas following a phase II study.<sup>75</sup> A randomized study also demonstrated superior efficacy to procarbazine in recurrent GBM.<sup>76</sup>

Temozolomide for newly diagnosed GBM has been studied both when given before RT<sup>77</sup> and when combined with RT in various dosing schedules.<sup>78,79</sup> Its role for newly diagnosed GBM was established by Stupp et al<sup>39,40</sup> on the basis of the EORTC 26981/22981 and NCIC CE.3 trial (Figure 27-4). In

this Phase III multicenter study, 573 patients with newly diagnosed GBM received RT alone or RT with concurrent temozolomide followed by six adjuvant cycles of temozolomide. The patients who received the combined-modality regimen had significantly longer OS and PFS without significantly more toxicity (Table 27-1). The 5-year OS was 10% among those receiving temozolomide versus 2% among those receiving RT alone ( $p < 0.0001$ ).<sup>39</sup> Patients in the most favorable RPA class had a 5-year OS rate of 28% following combined therapy.<sup>39</sup> In a companion paper, Hegi et al<sup>41</sup> reported that methylation of the promoter for the O<sub>6</sub>-methylguanine DNA methyltransferase (*MGMT*) gene, which encodes the DNA repair enzyme O<sub>6</sub>-alkylguanine DNA alkyltransferase (AGT or AGAT, but now commonly also referred to as *MGMT*), was correlated with prolonged survival and patients with *MGMT* methylated tumors benefited the most from temozolomide.

*MGMT* repairs DNA damage induced by temozolomide, and methylation of the *MGMT* promoter silences expression of the protein, thereby accentuating the antineoplastic effects of temozolomide. However, the mechanism by which *MGMT* promoter methylation leads to an improved outcome is more complex. For example, some patients with tumors that did not demonstrate *MGMT* methylation also benefited from temozolomide although it is increasingly recognized that the initial test probably scored some “methylated” tumors as either “unmethylated” or “unknown.”<sup>39,41</sup> Accordingly, it remains unclear whether *MGMT* analysis should categorically alter treatment, although this situation remains somewhat fluid. In addition, patients with tumors harboring methylated *MGMT* survived longer following treatment with RT alone than patients who did not have tumors harboring methylated *MGMT* treated identically.<sup>39,40</sup> Others reported similar findings in GBM<sup>80</sup> and other malignant gliomas.<sup>81</sup> Moreover, *MGMT* protein expression by immunostaining does not predict outcome.<sup>82</sup>

Several groups have explored intensifying the temozolomide dosing schedule in an attempt to overcome *MGMT*-mediated resistance.<sup>83,84</sup> The intensified regimens are designed to deplete *MGMT* activity as suggested by previous studies.<sup>85</sup> RTOG 0525 was a Phase III randomized placebo controlled study that compared standard temozolomide dosing following completion of radiotherapy (150 mg/m<sup>2</sup> to 200 mg/m<sup>2</sup> body surface area days 1 to 5 of 28) versus an intensified regimen (75 mg/m<sup>2</sup> to 100 mg/m<sup>2</sup> body surface area days 1 to 21 of 28). This prospectively validated that *MGMT* promoter methylation is a favorable prognostic factor regardless of treatment.<sup>86</sup> However, “dose-dense” temozolomide was more toxic than standard dosing and did not significantly alter PFS or OS regardless of *MGMT* status.<sup>86</sup>

Therefore, *MGMT* promoter methylation is prognostic but the mechanism remains unclear. In addition, there are now several different methodologies to test for *MGMT* promoter methylation, which may lead to discordant results.<sup>87</sup> It is possible that *MGMT* is a marker of more global hypermethylation and is only one of multiple genes mechanistically involved in resistance to alkylator chemotherapy and prognosis in tumors harboring the recently described Glioma CpG island methylator phenotype (G-CIMP).<sup>88,89</sup>

Another major area of investigation has been the use of vascular endothelial growth factor receptor (VEGFR) signaling inhibitors. Bevacizumab (Avastin) is a monoclonal antibody against VEGF that competitively inhibits binding of the ligand to VEGFR and targets tumor vascularity. It is the most widely studied of these antiangiogenic strategies.

Based on encouraging response rates and prolongation of PFS in recurrent GBM, two major Phase III studies, RTOG 0825 and Avastin in Glioblastoma (AVAglio) sponsored by F. Hoffmann La Roche, were launched nearly simultaneously.

Following maximal safe surgical resection, both randomized patients to receive RT and temozolomide plus either bevacizumab or placebo. Although there were subtle differences in trial design with respect to extent of resection (e.g., biopsy-only patients not permitted in RTOG 0825 but allowed in AVAglio, timing of treatment, etc.), both demonstrated prolongation of PFS (median 10.7 versus 7.3 months,  $p = 0.007$  for RTOG 0825; median 8.4 versus 4.3 months,  $p < 0.001$  for AVAglio).<sup>90,91</sup> However, neither demonstrated a difference in OS (median 15.7 versus 16.1 months,  $p = 0.21$  for RTOG 0825; median 16.8 months versus 16.7 months for AVAglio,  $p = 0.10$ ). Both permitted cross-over from placebo to bevacizumab that was offered as part of the study design to participants in RTOG 0825 and permitted but not offered routinely in AVAglio.

These results have not categorically settled the issue of whether bevacizumab should be used for newly diagnosed GBM. In RTOG 0825, the prolongation of PFS did not meet the prespecified statistical level (30% reduction in hazard,  $p = 0.004$  required for significance), whereas it did for AVAglio (23% improvement,  $p = 0.01$  required for significant difference in PFS). In addition, quality of life measures in RTOG 0825 did not demonstrate a “Net Clinical Benefit,” in fact it was worse for those who received bevacizumab, whereas improvement was observed in AVAglio.<sup>90,91</sup> In the context of these results, some practitioners consider using bevacizumab for patients with unresectable large deep tumors with surrounding edema, and especially patients with poor performance status, but such patients would have been excluded from the Phase III trials.

Other antiangiogenic therapies also have not improved survival. For example, the EORTC in collaboration with the Canadian Brain Tumor Consortium conducted the Phase III CENTRIC (Cilengitide in combination with Temozolomide and Radiotherapy In newly diagnosed glioblastoma Phase III randomized Clinical trial) study to evaluate the integrin inhibitor cilengitide that has reported antiangiogenic properties.<sup>92</sup> Based on encouraging Phase II results among the subset of patients with *MGMT* methylated tumors,<sup>93</sup> CENTRIC randomized such patients with newly diagnosed GBM to standard RT and temozolomide with or without cilengitide.<sup>94</sup> Median survival was unchanged (26.3 months in both arms, hazard ratio [HR] 1.02,  $p = 0.86$ ).<sup>94</sup> There was also no significant improvement in PFS (13.5 months versus 10.7 months, HR 0.93,  $p = 0.48$ ) as evaluated by the treating investigator.<sup>94</sup> A study of cediranib for newly diagnosed GBM (RTOG 0837) is ongoing; however, the failure of cediranib to demonstrate meaningful efficacy in recurrent GBM is concerning.

Two studies have evaluated antiangiogenic therapy in particular for patients with *MGMT* unmethylated tumors. The ongoing CORE (Cilengitide in patients with newly diagnosed glioblastoma multiforme and unmethylated *MGMT* gene promoter) randomized such patients to RT and temozolomide with or without cilengitide. Results are not available yet. The German GLARIUS Phase II trial randomized cases with unmethylated *MGMT* 2:1 to RT and concurrent bevacizumab followed by maintenance temozolomide for six cycles.<sup>95</sup> The primary endpoint was 6-month PFS determined by central review (generally considered somewhat unconventional), with 80% power to detect an increase from 40% to 60%. Results favored the bevacizumab arm (79.6% versus 41.3%,  $p < 0.0001$ ). Median PFS (9.7 versus 6.0 months, HR 0.3,  $p < 0.0001$ ) and OS (16.6 versus 14.8 months, HR 0.60,  $p = 0.031$ ) also significantly favored the experimental arm.<sup>95</sup> These results require maturation and further validation, but begin to suggest a subgroup of patients who may benefit from addition of bevacizumab containing chemotherapy in lieu of temozolomide for newly diagnosed GBM. Notably, OS did not favor the bevacizumab group in RTOG 0825 or AVAglio,<sup>90,91</sup> but these trials were not intended for comparison.

## Anaplastic Gliomas

Anaplastic astrocytomas, anaplastic oligodendrogliomas, and anaplastic oligoastrocytomas represent the most common WHO grade III tumors.<sup>1,21</sup> In anaplastic gliomas, resection appears to improve survival relative to biopsy, as it does for GBM.

### Anaplastic Astrocytic Neoplasms

It is generally accepted that RT should be administered postoperatively for astrocytomas. In a German study (NOA-04), early analysis demonstrated that survival was equivalent whether chemotherapy or RT was used first among patients with anaplastic astrocytomas, oligodendrogliomas, and mixed tumors.<sup>12</sup> However, time to progression following RT was longer than after chemotherapy, and initial radiation therapy achieved more complete and partial responses than initial chemotherapy, suggesting the superiority of RT.<sup>96</sup> In addition, the data were relatively immature at initial publication, and longer follow-up may demonstrate the importance of primary RT more fully among anaplastic astrocytomas, or mixed oligoastrocytomas without 1p19q codeletion.

Regarding chemotherapy, Combs et al<sup>97</sup> reviewed the outcome of 191 patients with grade III astrocytic tumors treated at the University of Heidelberg with either RT alone or RT in combination with temozolomide during a 20-year period (from 1988 to 2007). In this retrospective study, no significant advantage in rates of OS or PFS could be attributed to the combination. RTOG trial 9813 randomized patients with anaplastic astrocytomas (or oligoastrocytomas) to RT with concurrent nitrosourea (carmustine or lomustine) or with temozolomide, and results are pending.

The ongoing Concurrent vs. Adjuvant Temozolomide for NON 1p19q co-deleted anaplastic gliomas, also called EORTC 26053-22054 (CATNON) Intergroup trial randomizes patients to receive postoperative RT alone, concurrent temozolomide and RT without adjuvant temozolomide, RT (without concurrent temozolomide) followed by adjuvant temozolomide, or RT with both concurrent and adjuvant temozolomide (Figure 27-5). Although technically this study allows any WHO grade III glioma without 1p/19q codeletion, the majority of the tumors will be anaplastic astrocytomas.

### Anaplastic Oligodendroglial Tumors

Long-term follow-up is now available for patients enrolled on RTOG 94-02<sup>10,98</sup> and EORTC 26951.<sup>11,99</sup> In these studies, radiation was compared to radiation with PCV chemotherapy. The RTOG trial entailed administration of chemotherapy before irradiation (intensified PCV<sup>100</sup> for up to four cycles in the combined-modality arm) whereas the reverse sequence (i.e., RT alone versus 59.4 Gy followed by up to six cycles of standard dose PCV) was used in the EORTC trial. With median

follow-up in excess of 10 years in both studies, there was a dramatic improvement in OS associated with combined chemotherapy and radiotherapy (irrespective of sequence) among patients with anaplastic oligodendroglioma or anaplastic mixed oligoastrocytoma whose tumors contain allelic loss of chromosomes 1p and 19q, compared with radiation alone. For example, in RTOG 9402, median survival was 14.7 years versus 7.3 years ( $p = 0.03$ , HR 0.59 for chemoradiotherapy) and in EORTC 26951 median survival was not reached versus 9.3 years ( $p = 0.0594$ , HR 0.56 for chemoradiotherapy). In addition, patients with *IDH* mutant but not 1p19q codeleted tumors also benefited from chemotherapy, although the magnitude was lower than for those with tumors that harbored both codeletion and *IDH* mutation.<sup>101</sup> Those with *MGMT* promoter methylation<sup>87</sup> or *ATRX* expression<sup>101</sup> may also benefit regardless of 1p19q deletion status.

The applicability of these findings in an era where PCV is no longer popular remains debatable, especially because temozolomide has almost entirely replaced PCV in routine practice<sup>102</sup> despite the lack of a clear efficacy equivalence. What is clear, however, is that RT alone is inadequate for treatment of patients with codeleted tumors, and likely those with *IDH1* or *IDH2* mutated tumors, regardless of deletion status.

In addition, the role of RT for newly diagnosed anaplastic oligodendroglioma is becoming the subject of controversy because of the tumor's reported sensitivity to chemotherapy,<sup>100</sup> especially tumors with 1p/19q codeletion.<sup>103</sup> Neither RTOG 9402 nor EORTC 26951 used chemotherapy alone, which was recommended by 42% of clinicians (typically with temozolomide)<sup>13</sup> and used in 55% of patients from 2005 to 2007 in a retrospective series of codeleted tumors, without prospective data supporting such usage.<sup>102</sup> The ongoing CODEL (for 1p/19q CO-DEleted tumors) trial now randomizes patients to RT followed by PCV versus RT plus concurrent and adjuvant temozolomide, versus temozolomide alone (Figure 27-6).

The CATNON and CODEL study designs are premised on the belief that the 1p/19q chromosomal status may be more important than the histologic subtype for WHO grade III lesions. However, scientific advances in the interim may outpace the questions posed by these trials as it becomes apparent that *MGMT* promoter methylation<sup>81,87</sup> and *IDH* gene mutation<sup>12,18,101</sup> are also powerful markers of outcome in anaplastic gliomas. There is a clear need to move beyond histologic information (e.g., WHO subtyping) because important advances in prognostication have been made.<sup>104</sup>

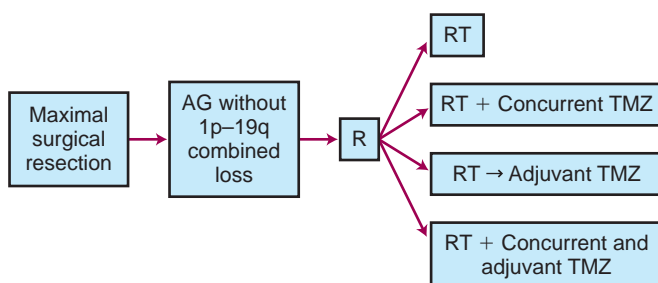

## Special Topics

### Toxicities of Radiation Therapy

Acute and late effects of irradiation, including brain necrosis are discussed in a subsequent section on [Irradiation Techniques and Toxicities](#).<sup>45,97,105-107</sup>

### Elderly Patients with GBM

More than 44% of GBMs occur in patients older than 65 years of age,<sup>1</sup> but prospective trials often exclude elderly patients.<sup>39,40</sup>

**Figure 27-5** Schema from the CATNON study (Intergroup phase III, EORTC 26-53, RTOG 0834). AG, Anaplastic glioma; R, randomization; RT, radiotherapy; TMZ, temozolomide.

**Figure 27-6** Schema from the CODEL trial (NCCTG NO0557/RTOG 0670). PCV, Procarbazine; TMZ, temozolomide.

Because these patients often have a worse outcome than younger patients, there has been some uncertainty with regard to the aggressiveness of treatment, and the definition of “elderly” is highly variable.

A Finnish randomized study of 30 patients older than age 65 years with imaging consistent with malignant gliomas demonstrated longer median survival following craniotomy than following biopsy (5.7 versus 2.1 months;  $p = 0.035$ ).<sup>32</sup> The Association of French-Speaking Neuro-Oncologists<sup>106</sup> conducted a randomized trial comparing RT alone (50 Gy in conventional fractionation) versus supportive care among patients older than 70 years of age. The trial was discontinued after 85 patients were registered when it became apparent that RT was associated with a statistically advantageous outcome (median survival time, 29 versus 17 weeks;  $p = 0.002$ ).

Efforts to abbreviate the duration of RT have been conducted. For example, a randomized study in patients older than age 60 years demonstrated that 40 Gy in 15 fractions was not inferior to 60 Gy in 30 fractions.<sup>107</sup>

A Phase II study of temozolomide alone in 32 patients older than age 70 years with newly diagnosed GBM demonstrated a response rate of 31%, median PFS time of 5 months and median survival time of 6.4 months, comparable to RT alone.<sup>108,109</sup> A single-arm 77-patient Phase II study for those older than age 70 with poor performance status (Karnofsky Performance Status [KPS] <70)<sup>110</sup> demonstrated median survival of approximately 6 months, with 26% becoming functionally independent (KPS at least 70).<sup>111</sup> Among those with *MGMT*-promoter methylated tumors (13 of 31 tested) median OS was approximately 7 months, and *MGMT* status was a statistically significant prognostic factor.<sup>111</sup>

In the NOA-08 trial conducted by the German Neuro-Oncology Working Group,<sup>112</sup> 373 patients older than age 65 with KPS of at least 60 with anaplastic astrocytoma or GBM (in 89%) were treated following randomization with RT (60 Gy) or an intensive schedule of temozolomide (100 mg/m<sup>2</sup> days 1 to 7 and 15 to 21 of every 28) without RT. If patients did not tolerate treatment or if they demonstrated progression, then cross-over (or surgical intervention) was triggered. Survival was slightly shorter following chemotherapy alone (8.6 months versus 9.6 months), but did not reach the prespecified statistical endpoint for declaring it inferiority (i.e., it was non-inferior, based on accepting a certain level of survival loss designated as “noninferior”). Among patients with *MGMT* unmethylated tumors, RT was statistically superior (4.6-month versus 3.3-month event-free-survival). In addition, in *MGMT*-methylated cases, treatment with temozolomide was superior (8.4-month versus 4.6-month event-free survival). Analyzed differently, *MGMT* status did not influence event-free survival following RT (4.6 months regardless of *MGMT* status). However, *MGMT* status clearly and strongly influenced event-free survival following temozolomide alone (8.4 months versus 3.3 months for methylated versus unmethylated). Accordingly, among those with *MGMT*-methylated tumors, RT alone was an inferior treatment to temozolomide, and similarly, temozolomide alone was an inferior treatment to RT in those with unmethylated tumors. Many have presumed by implication that temozolomide in lieu of RT could be considered a reasonable treatment strategy in the elderly, but this supposition does not take into account the fact that results with combination RT and temozolomide are superior in almost all trials, and in the U.S. trials, even patients in their 80s were enrolled. Accordingly, monotherapy should be reserved for patients with poor KPS. Further, the intense schedule of temozolomide was excessively toxic and more standard schedules of temozolomide, commonly used in the United States were not studied in this trial,<sup>112,113</sup> and as eluded to previously, the combination of RT and temozolomide (the

standard of care for patients younger than age 70 in Europe, and no age limit imposed in U.S. clinical trials, including enrollment patients, even in their 80s, as long as KPS was >70)<sup>39,40</sup> was not studied. It must further be underscored that NOA-08 had a noninferiority design, which included a definition of inferiority of temozolomide as a greater than 25% difference in survival endpoints, which arguably represents too much latitude and insufficient statistical rigor to allow clinicians to conclude that a new standard of care has emerged, especially given that there are few other comparable scenarios in oncology, where 25% loss of survival is accepted as noninferior.

In a Phase III trial from the Nordic Clinical Brain Tumour Study Group, 291 patients were randomized to standard dose temozolomide, standard (60 Gy) RT, or hypofractionated RT (10 fractions of 3.4 Gy each), and similar to the NOA-08 trial, there was no combined-modality therapy arm.<sup>114</sup> The trial has been criticized for its inclusion criteria of 60-year-olds under the rubric of “elderly” in view of the fact that the median age for the diagnosis of GBM is closer to 65 in the contemporary era.<sup>115</sup> Nonetheless, in an unplanned posthoc subset analysis of patients older than 70 years of age ( $n = 123$ ), standard irradiation was associated with inferior survival in comparison to the other therapeutic arms; there was no difference in outcome between temozolomide and short-course RT, with fewer cytopenic toxicities in the short-course RT arm. The Nordic trial, much like the German study, revealed that *MGMT*-promoter methylation predicted for better outcomes in those treated with temozolomide alone, and once again it must be noted that the trial was not initially powered for this assessment as a primary observation. These trials are still open to interpretation at this juncture. The case could be made that for those patients in whom for reasons of poor performance status or inability to commute for long-course RT, temozolomide alone or short-course RT without temozolomide is an acceptable alternative; for patients who might be at higher risk of infection, short-course RT would induce fewer cytopenic episodes and might actually be preferred over temozolomide. For *MGMT*-methylated tumors in patients for whom daily radiation treatments for 6 weeks or so may impose unacceptable burden, temozolomide alone could be considered. This is not to say that RT is not an effective option for elderly patients, especially for patients with unmethylated-promoter *MGMT*. Indeed, an important next step will be to investigate chemoradiation strategies using a shortened course of irradiation, especially in the elderly poor KPS subset of patients; this is the subject of an ongoing trial by the EORTC and NCI Canada (NCT00482677).

It should also be noted that intravenous temozolomide has recently become available as an option for elderly or otherwise impaired patients who cannot swallow capsules or comply with an oral regimen.<sup>116</sup>

### Pseudo-Progression

Pseudo-progression confounds interpretation of imaging performed in the first several months following completion of RT. Descriptions of “pseudo-progression” appeared as early as 1979, when Hoffman et al<sup>117</sup> described patients treated with RT and carmustine. Among patients thought to have experienced disease progression immediately following irradiation, nearly half were shown to have improvement or at least stabilization on subsequent brain imaging.

A report in 2004 described that approximately one third of patients with gliomas stabilized or improved with no change in management.<sup>118</sup> Chamberlain et al<sup>119</sup> reported histologically proven treatment injury rather than disease progression in approximately 50% of patients with symptomatic resectable lesions felt to represent worsening disease

following concurrent RT and temozolomide. The incidence of pseudo-progression has been reported to be as high as 75%, in selected subsets of patients with GBM.<sup>84,120,121</sup> Pseudo-progression rather than “true” progression may also correlate with *MGMT*-promoter methylation,<sup>120</sup> although this has not yet been prospectively validated.

Multiple imaging techniques have been explored to delineate radiographic pseudo-progression from true progression.<sup>120,122-126</sup> However, at this time, histologic analysis is the only validated method of distinguishing the two diagnoses, and even that has its limitations because of sampling issues, and difficulty in interpreting tumor cell viability posttreatment.<sup>127</sup>

It is presumed that the incidence of pseudo-progression is higher following concurrent RT and temozolomide than that following RT alone, although supportive evidence is equivocal.<sup>128</sup> As chemoradiotherapy is now the accepted standard of care for newly diagnosed GBM, no prospective study is likely to study this definitively. One approach to dealing with this issue involves using the MRI study done following RT as a new baseline, unless there is surgical documentation of recurrent disease or clear worsening outside of the RT portal. This remains an area of active study.<sup>129</sup> It is also worth noting that the “stabilization” of the peritumoral vasculature induced by antiangiogenic agents can possibly lead to a reduction in the pseudo-progression event rate, and has sometimes been used to manage florid imaging changes, with or without clinical deterioration.

## RECURRENT DISEASE

### Chemotherapy

Efforts to treat recurrent disease with single agents, either cytotoxics or molecular-targeted agents, have generally been unsuccessful, at least in part because of the innate resistance, poor drug penetrability, and molecular complexity of the disease.<sup>130</sup> Some studies suggest the key may lie in identifying the patients most likely to respond based on molecular profiling of tumor tissue at recurrence.<sup>131</sup>

An exception is the use of agents that target vascular endothelial growth factor (VEGF) or VEGFRs. Bevacizumab, a monoclonal antibody against VEGF, is the most widely studied of these antiangiogenic strategies.

The “BRAIN” trial was a noncomparative Phase II study for recurrent GBM that randomized 167 patients to either bevacizumab alone or bevacizumab combined with irinotecan,<sup>132</sup> the latter regimen adopted from activity of that combination in colon cancer.<sup>133</sup> The 6-month PFS was 43% with bevacizumab and 50% with bevacizumab plus irinotecan.<sup>132</sup> Similar results were seen in a single-arm Phase II study conducted by the NCI.<sup>134</sup> None of these trials however provided categorical evidence of improved OS.

These results are far superior to those of prior available therapies. For example, the 6-month PFS following carmustine is approximately 15% to 20%.<sup>135</sup> Emerging data from the randomized Dutch BELOB (BEvacizumab vs. LOMustine in glioblastoma, Or Both) study demonstrate the superiority of bevacizumab (10 mg/kg days 1 and 15 of 28) combined with lomustine (90 mg/m<sup>2</sup> to 110 mg/m<sup>2</sup> every 6 weeks) versus either alone in terms of 6-month PFS (16% for bevacizumab, 13% for lomustine alone, >40% for lomustine with bevacizumab).<sup>136</sup> Based on these results, EORTC 26101 has been redesigned to compare lomustine alone (110 mg/m<sup>2</sup>) versus bevacizumab with lomustine (90 mg/m<sup>2</sup>), specifically seeking a survival benefit in a Phase III context for recurrent GBM.

Trials of other VEGF/VEGFR inhibitors have been negative. For example, REGAL (Recentin in Glioblastoma Alone

and With Lomustine) was a Phase III trial<sup>137</sup> that tested efficacy of Recentin (cediranib), a direct oral pan-VEGFR inhibitor after a prior promising Phase II study.<sup>138</sup> An interim analysis demonstrated median PFS was longer following cediranib (92 days) or cediranib and lomustine (125 days) than lomustine (plus placebo, 82 days). However, median OS was not longer with cediranib (8.0 months versus 9.4 months versus 9.8 months), and the PFS benefit did not reach the prespecified improvement goal; accordingly, the trial was declared negative and accrual terminated.<sup>137</sup>

Therefore, despite increased response rates and improved PFS, to date there are no data clearly demonstrating a survival advantage for the use of bevacizumab, and its major potential toxicities include thromboembolic disease, hemorrhagic consequences, and hypertension. In addition, almost all salvage treatments following progression on bevacizumab are ineffective,<sup>41,139</sup> and therefore, the timing of bevacizumab for either first or later recurrence remains controversial. Recent data suggest that deferring bevacizumab to a second or later recurrence does not shorten survival.<sup>140</sup> The potential toxicity, as well as the fear of inducing a more invasive tumor phenotype also tempers enthusiasm for use of this agent in newly diagnosed disease, especially in light of lack of survival benefit from the RTOG 0825<sup>90</sup> and AVAglio trials.<sup>91</sup>

### Alternating Electric Fields

Finally, one nonchemotherapy approach has been explored using alternating electric fields, tumor treatment fields (TTF) generated by a current source on the scalp (NovoTTF). This therapy is hypothesized to affect the mitotic spindle and thereby reduce proliferation. A Phase III trial suggested non-inferiority when compared to any one of several possible physician-chosen chemotherapy regimens (median survival 6.6 months versus 6.0 months, HR 0.86 [95% CI, 0.66 to 1.12],  $p = 0.27$ ; 6-month PFS 21.4% versus 15.1%,  $p = 0.13$ ) with less toxicity than chemotherapy.<sup>141</sup>

Favoring a role for the device in treatment of glioblastoma, in addition to the similarity of survival and fewer side effects, more responses were seen in the TTF arm, although the difference was not significant and the response rate was low regardless of treatment. These results led to accelerated FDA approval. It should also be noted that 31% of patients received bevacizumab as the comparator chemotherapy during treatment on study, and approximately 20% of patients in both arms had a bevacizumab refractory tumor, suggesting benefit of the device in such patients.

However, it should be noted the trial was formally negative. The primary endpoint was improvement in survival. The statistical design had 80% power to detect a 60% increase in survival (HR 0.63,  $p \leq 0.05$ ), and this was not achieved. The study was neither designed nor powered for a noninferiority endpoint, and the lack of a difference in survival in this study is not necessarily the same as true noninferiority.

In addition, the requirement for device approval is less stringent than for a drug, and the trial design and results have been heavily criticized. For example, there was no placebo device used as a control. One explanation is the questionable ethics of randomizing patients to no treatment whatsoever had the design been chemotherapy compared with NovoTTF compared with placebo device. However, that could have been ameliorated by randomizing patients to a specific chemotherapy (such as a nitrosourea or bevacizumab or both) in combination with either NovoTTF or placebo device.

Therefore, a clear interpretation remains elusive. The device appears reasonably safe, and it may well be that NovoTTF was noninferior to various chemotherapies. However, it is equally plausible that neither the device nor the chemotherapies were

beneficial to the patients. A Phase III study for newly diagnosed GBM (without placebo control) is ongoing, and a trial evaluating survival benefit in bevacizumab refractory GBM is being designed through the RTOG Foundation.

## Reirradiation

Focal RT approaches are often employed with limited volume recurrences. In a retrospective analysis of 95 patients with recurrent gliomas treated with the GlioSite device, the median survival time was 36 weeks.<sup>142,143</sup> However, whether this is a function of true benefit or patient selection has not been determined.

Fractionated RT to treat larger-volume recurrent disease has also been employed. Although there has been speculation from animal studies that neural tissue will recover from previous irradiation to a large extent once some time has elapsed (e.g., 1 year to 3 years),<sup>144</sup> no firm data quantify the degree to which one can assume that a “dose discount” exists. It is most likely that the damage from reirradiation is underestimated because the majority of patients do not live long enough to express such damage. A small study showed good short-term tolerance to intensity-modulated radiation therapy (IMRT) delivered in six daily fractions of 5 Gy each.<sup>145</sup> A recent single-arm trial from the Memorial Sloan Kettering Cancer Center (MSKCC) demonstrated reasonable safety and efficacy of combined bevacizumab and reirradiation using IMRT for small recurrent malignant gliomas.<sup>50</sup> No radionecrosis was observed and survival appeared to be prolonged relative to historic controls, suggesting that bevacizumab may not only treat radionecrosis<sup>146</sup> but might protect against it. Another approach was recently reported by investigators from Jefferson Medical College<sup>147</sup> who treated 147 patients with recurrent high-grade glioma to 35 Gy in 3.5-Gy fractions with stereotactic radiation therapy. This hypofractionated stereotactic radiation therapy (HSRT) approach was associated with a median survival time in excess of 10 months.

Based on the promising results from the MSKCC and Jefferson trials, RTOG 12-05 was recently opened for patients with recurrent GBM. The Phase II study, which will enroll approximately 180 patients who are bevacizumab-naïve with recurrent disease, compares concurrent bevacizumab plus reirradiation (using a hypofractionated RT schema of 35 Gy in 10 fractions) to bevacizumab alone.

## IRRADIATION TECHNIQUES AND TOXICITIES

Whole-brain radiation therapy (WBRT) has been replaced with partial brain techniques by consensus for almost all gliomas. Although the dose computation component of treatment planning requires CT imaging, effective image registration with MRI has made this the modality of choice for contouring. The notion of a dedicated MRI simulator has also been proposed as a valuable adjunct in the radiotherapeutic management of high-grade gliomas.<sup>148</sup> However, treatment plans based only on MRI are not able to take into account tissue electron-density variations, which may lead to slightly inaccurate dose calculations.

Patients are usually simulated after surgical wound apposition is reasonably stable and free of infection (generally, 10 days to 14 days after the operation). An immobilization mask is fashioned to reduce motion during and between fractions. The planning CT scan is extended to encompass the head and neck region to allow sufficient anatomic areas for proper image fusion and generation of high-quality digitally reconstructed radiographs (DRRs) and to permit the introduction

of noncoplanar beams; ideally, the slice thickness should match that of the MRI used for fusion.

For high-grade gliomas, especially GBM, T1 contrast-enhanced sequences are used to define the gross tumor volume (GTV) and the T2 or FLAIR sequences plus a margin define the microscopic disease extent, or clinical target volume (CTV), which reflects the bulk of microscopic infiltration. To arrive at a planning target volume (PTV), both organ motion and setup error must be taken into account. Organ motion in the brain is quite minimal during therapy (e.g., <1 mm). The PTV may be further modified to exclude normal tissue in areas where gliomas are unlikely to infiltrate. Bokstein et al<sup>149</sup> recently demonstrated that when anatomic barriers such as the temporal bone can serve as a border to impede tumor spread, failure is likely to be seen in less than 5% of cases even when the customary 2-cm margins are *not added* to the abnormalities seen on MRI (Figure 27-7).

In general, there are two major schools of thought (with numerous institutional variations based on these) that provide guidance for the prescription of the radiation regimen. The RTOG approach is a biphasic technique that includes an initial PTV (PTV 1) followed by a second PTV (PTV 2) that represents the cone down. In the lexicon of the RTOG, the PTV 1 includes the T2 or FLAIR CTV with a margin and is treated to 46 Gy in 2-Gy fractions. The PTV 2 includes the T1-enhancing GTV with a margin and is treated to an additional 14 Gy. The EORTC recommends a single-phase technique using one treatment volume throughout the course of therapy. Table 27-2 shows the partial brain volumes advocated by several cooperative groups for the successive phases of partial brain irradiation.

With the advent of functional imaging tools (e.g., functional MRI [fMRI]) it may be possible to specifically modify irradiation doses to functional brain areas. Figure 27-8 displays a treatment plan wherein the region governing motor control (e.g., finger tapping) is delineated to enable an accounting for dose deposition. In this case, this region in the right hemisphere (i.e., governing tapping by the left upper extremity) is included in the high-dose region but the contralateral side is well spared; a major caveat here is that the dose-response relationships for various functional subvolumes in the brain are largely unknown, and therefore, this

**Figure 27-7** Lesion that could be treated without a full complement of margins because of anatomic barrier of the temporal bone.

information is of little practical dosimetric usefulness at this point in time.

In RTOG 08-25, it was noteworthy that approximately 80% of patients, irrespective of treatment arm, received IMRT. Lorentini et al<sup>150</sup> performed meticulous comparison of IMRT and three-dimensional (3D) conformal irradiation among patients treated for GBM. The IMRT plans consistently provided better target coverage than their 3D-conformal counterparts and yielded a statistically significant dose reduction to the healthy brain. The authors suggested that IMRT represents the superior technique when there are more than two regions of overlap between organs at risk (OAR) and the PTV.

Table 27-3 summarizes the tolerance of various OAR according to the new Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) guidelines. Lawrence et al<sup>151</sup> postulated that the original estimates of Emami et al,<sup>152</sup>

TABLE 27-2 Radiotherapy Volume Used in Current Clinical Trials		
RT Dose	Block Edge Dosimetry Margin*	Source for RT Dose
46 Gy	T2 + 2 cm	RTOG
14 Gy	T1 + 2.5 cm	
60 Gy†	T1 + 2-3 cm	EORTC
50 Gy	T2 + 2 cm	NCCTG
10 Gy	T1 + 2 cm	

3D, Three-dimensional; EORTC, European Organization for Research and Treatment of Cancer; Gy, Gray; NCCTG, North Central Cancer Treatment Group; RT, irradiation dose; RTOG, Radiation Therapy Oncology Group.  
 \*Both RTOG and EORTC prescribe dose to block edge (geometric) margin, whereas NCCTG prescribes dose to dosimetry (3D) margin.  
 †CENTRIC studies: either RTOG or EORTC volumes and RT doses are used, at individual physician discretion.

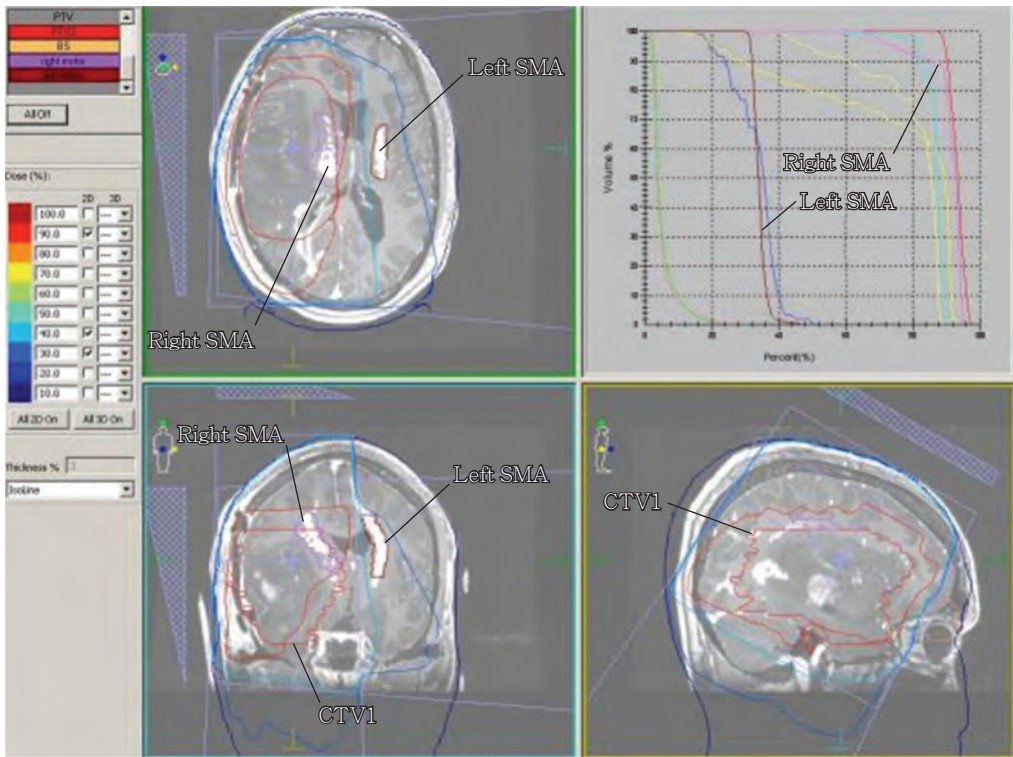

suggesting a 5% risk of chronic brain damage at 5 years when one third of the brain is irradiated to 60 Gy, were overly conservative. Instead, they hypothesized (Figure 27-9) that the dose correlated with a 5% risk of damage at 5 years following conventionally fractionated irradiation to the partial brain is 72 Gy, but data regarding subvolume and substructure sensitivity are not included in the QUANTEC assessment.

There may sometimes be a tendency to overlook structures that, if damaged, would have led to noncatastrophic sequelae. For instance, although it is true that radiation-induced cataracts are easily repairable,<sup>156</sup> avoidance of entrance and exit dose to the eye may be a relatively simple means of preventing not only cataracts but also conjunctivitis and a dry eye, by sparing the lacrimal gland. Similarly, when one contours the ear canals, there is now a greater awareness of the risks of developing otitis externa as well as otitis media.

There are reports of cytopenias arising from cranial irradiation even among patients who have not received chemotherapy.<sup>157</sup> The hypothesized mechanism of this is either irradiation of circulating blood within the radiation portals, injury to marrow in the cranium, or the use of vertex beams that exit through the spinal axis. The latter mechanism has also been invoked to explain radiation-induced fatigue by some investigators.<sup>158</sup>

For tumors located in the temporal lobes, the exit dose to the parotid gland may cause xerostomia. Tumors in such locations may be best treated with IMRT because one of the success stories of the application of IMRT to the head and neck region is indeed the elimination of this bothersome side effect.

Overall, the aim is to achieve the treatment plan that most closely approximates the defined volumes and thereby produces the most conformal plans. Relatively low energy beams (e.g., 6 MV) are typically employed. In contrast to the irradiation of varying organs containing primary tumors, it is

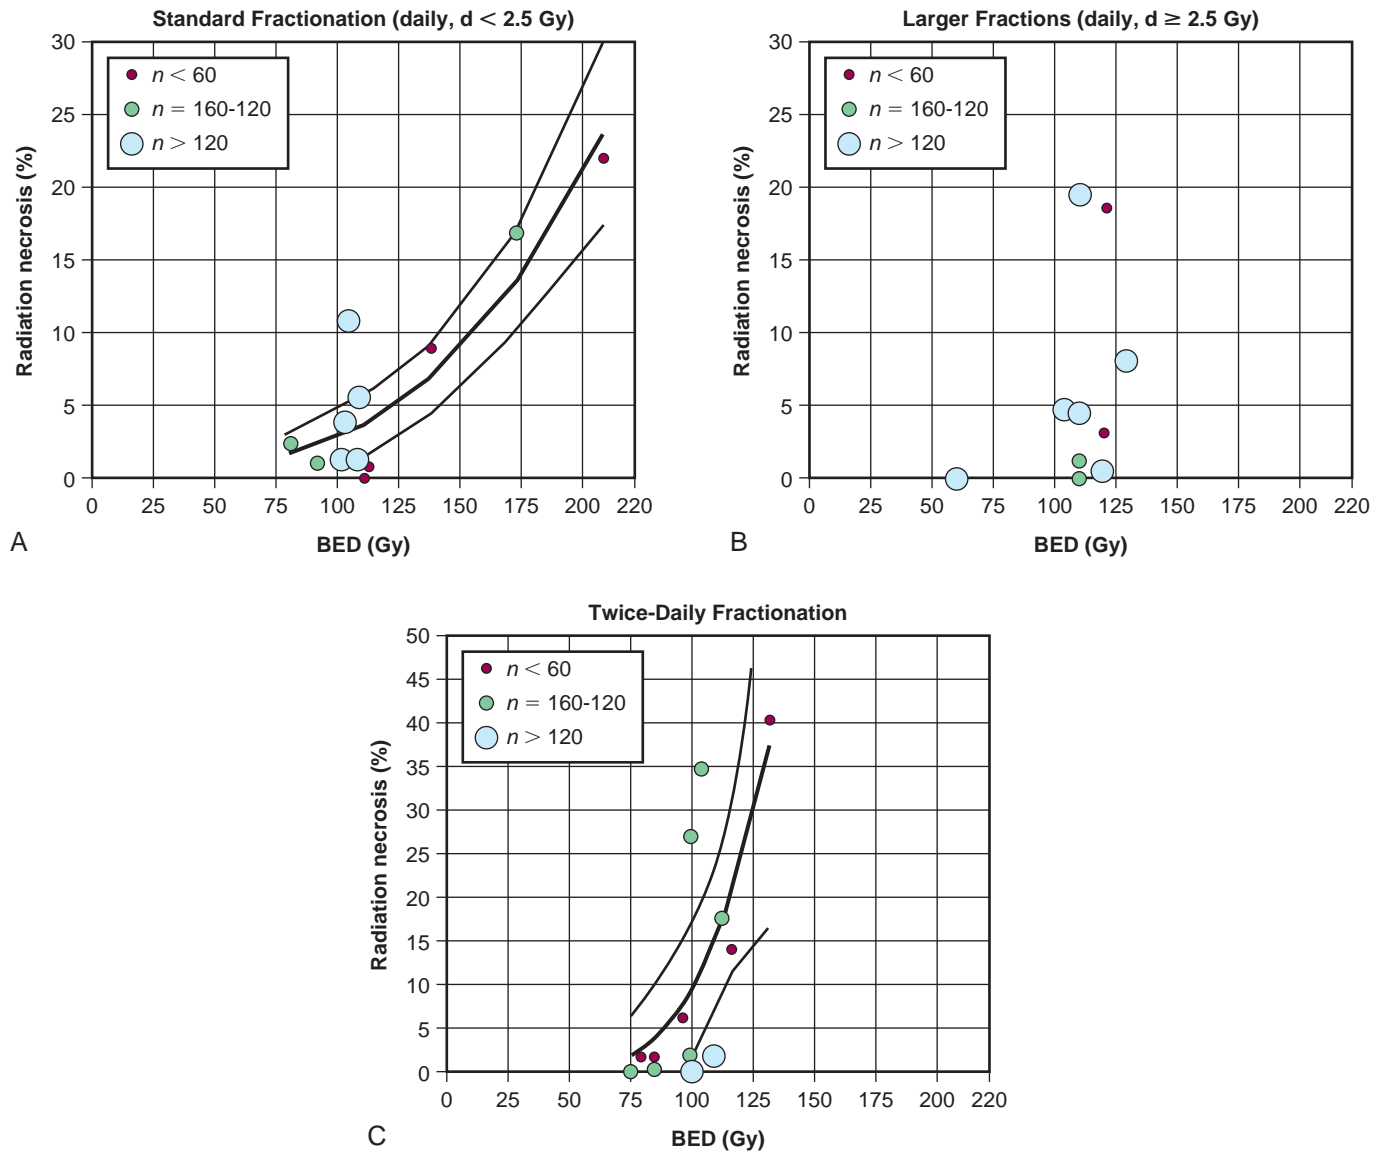

**Figure 27-8** Treatment planning based on a functional MRI. Note delineation of the clinical target volume (CTV) as well as left and right somatomotor areas (SMA) controlling hand movements of the right and left upper extremities, respectively.

**TABLE 27-3** Selected Organs at Risk for Treatment Planning of Malignant Glioma

Organ	Dose Limit	Comments
Brain parenchyma <sup>151</sup>	72 Gy	Brain appears to be more sensitive to fraction size > 2 Gy and to twice-daily radiation therapy
Optic apparatus <sup>153</sup>	60 Gy	12 Gy for single-fraction radiosurgery
Brainstem <sup>154</sup>	54 Gy	59 Gy if small volumes (i.e., 1-10 mL)
Parotid gland <sup>155</sup>	20 Gy	Severe xerostomia vis-à-vis sparing of one parotid gland
	25 Gy	Severe xerostomia vis-à-vis sparing of both parotid glands

**Figure 27-9** QUANTEC data for central nervous system tolerance based on the study in Lawrence et al. Relationship between biologically effective dose (BED) and radiation necrosis after fractionated radiotherapy. The Lawrence figure was done with a nonlinear least-squares algorithm using MatLab software (MathWorks, Natick, Mass.). The nonlinear function chosen was the probit model (similar functional form to the Lyman model). Dotted lines represent 95% confidence levels; each dot represents data from a specific study (Lawrence Table 2);  $n$  = patient numbers as shown. **A**, Fraction size less than 2.5 Gy. **B**, Fraction size 2.5 Gy or larger (data too scattered to allow plotting of “best-fit” line). **C**, Twice-daily radiotherapy. impossible to recommend a single idealized beam arrangement for high-grade gliomas. In this context, the role of proton therapy is being explored to further reduce dose to surrounding tissue distal to the tumor.

### Miscellaneous Technique Issues

Despite the absence of level I evidence, IMRT is increasingly used, sometimes to escalate the dose and at other times to spare surrounding tissues or to explore the concomitant boost concept. However, clinical data supporting improved outcomes from IMRT in high-grade gliomas are essentially nonexistent.

Guidelines for tumor delineation and dose selection for WHO grade III gliomas are less well developed. In general, the FLAIR and T2 compartments are regarded as containing microscopic disease and therefore constitute the CTV. The typical dose is 59.4 Gy or 60 Gy in 1.8-Gy to 2-Gy fractions.

### Toxicities of Radiation Therapy

Acute radiation morbidity includes fatigue, erythema, alopecia, headache, and rarely, nausea with or without vomiting; these are generally not severe and are usually self-limiting.<sup>45</sup> Some have cautioned that the combination of cranial RT and phenytoin as well as other anticonvulsants could give rise to the Stevens-Johnson syndrome,<sup>159,160</sup> but this dermatologic emergency is an exceedingly rare event, and the causal association between the two has not been established.

Late effects of radiation (e.g., somnolence and, especially, cognitive impairments) are more worrisome and may become manifest many years later.<sup>161</sup> The impact of partial brain irradiation on neurocognitive decline continues to be a hotly debated topic. The confounding factor is always the extent to which there is baseline cognitive impairment or decreased mentation secondary to tumor. Hippocampal sparing may emerge as a method to reduce the risks of neurocognitive injury as it appears to do in the treatment of brain metastases with WBRT.<sup>162</sup>

Brain necrosis is a serious and uncommon late toxicity, and recently bevacizumab has been explored as a treatment.<sup>146</sup> In a small trial, all patients showed improvement of MRI abnormalities as well as a reduction in corticosteroid requirements following treatment with bevacizumab.<sup>163</sup>

We currently estimate the risk of normal tissue damage based on the most sensitive 5% of the population. Accordingly, we bias our recommendations in a manner that is not germane to most individuals, and preliminary efforts at predicting the likelihood of toxicities based on risk are ongoing.<sup>164,165</sup>

## TREATMENT ALGORITHM, CONTROVERSIES, CHALLENGES, AND FUTURE POSSIBILITIES

### Treatment Algorithm

For adults up to age 70 years with newly diagnosed GBM, the current standard of care is safe maximal surgical resection (with or without Gliadel wafer implantation) followed by concurrent EBRT (approximately 60 Gy in 30 fractions) with temozolomide and followed by at least 6 months of adjuvant temozolomide (Figure 27-4). For suspected progression that occurs within 3 months of completing RT, the possibility of pseudo-progression should be strongly considered.<sup>166</sup> Relapsed disease may be treated with re-resection, second-line chemotherapy, or experimental therapy in a clinical trial. Reirradiation is also a possibility but is used infrequently. Bevacizumab

is approved for relapsed disease, as are carmustine wafers and Gliasite brachytherapy.

For newly diagnosed anaplastic gliomas, RT is typically administered as part of the initial therapy. Some advocate chemotherapy first, especially in 1p19q codeleted anaplastic oligodendroglial tumors.<sup>12,13</sup> Based on randomized trials, RT before and after PCV chemotherapy is clearly superior to RT alone for patients with 1p19q codeleted anaplastic oligodendroglial tumors.<sup>98,99</sup>

### Controversies

Treatment for elderly patients (variably defined as older than 60, 65, or 70 years of age, depending on the study) remains controversial. Patients with a good performance status and few comorbidities are often treated according to the same algorithm used for younger patients. However, abbreviated radiotherapy courses appear to be noninferior<sup>107</sup> and are often employed. Temozolomide alone using standard rather than intensified dosing is a reasonable treatment strategy for elderly patients with MGMT-methylated tumors based on comparisons to RT alone, specifically in patients for whom combined-modality therapy is a significant challenge.<sup>112,114</sup> Definitive studies of combined RT and temozolomide restricted only to “elderly” patients have not been completed, and whether chemoradiation using a rapid course of RT is superior to RT or temozolomide alone is under investigation, but it must be borne in mind that the U.S. trials included patients even in their 80s when using combined-modality approaches.

Bevacizumab does not prolong survival when added to RT and temozolomide for newly diagnosed GBM.<sup>90,91</sup> Emerging data suggest that combining bevacizumab with nitrosourea therapy may be superior to bevacizumab or nitrosourea alone for recurrent GBM<sup>136</sup> and this is being further tested in Phase III study by the EORTC.

Treatment of anaplastic gliomas is an area of extreme controversy, with astrocytomas often treated as GBMs and a more variable approach used for oligodendrogliomas. Ongoing trials will attempt to define a standard algorithm based on the 1p/19q deletion status.

### Challenges

Local control of high-grade gliomas remains a vexing problem. In addition, the increased recognition of pseudo-progression as an entity and the possibility of pseudo-response to antiangiogenic therapy such as bevacizumab<sup>167</sup> complicate matters further. A revised set of consensus criteria were recently developed in part to address some of these issues.<sup>129,166</sup> Certainly, correlative clinical follow-up to provide the proper perspective on the health status of the patient will never be abandoned, because imaging will always represent an imperfect surrogate for survival. Although new developments in diagnostic imaging continue to hold out promise for resolution of the diagnostic dilemmas faced by the neurooncology team, to date even the most sophisticated imaging studies (e.g., FDG PET, MRS) have not provided a consistently reliable solution to these and other vexing problems.

### Future Possibilities

Prior dose-escalation trials for GBM, all conducted in the pretemozolomide era, have been uniformly negative beyond 60 Gy. However, it is conceivable that the notion of dose escalation now needs to be revisited in the backdrop of control of microscopic disease by temozolomide enhancing the effect of focal dose-escalation, as well as the potential radioprotection offered by bevacizumab.<sup>53</sup>

The 5-year OS from the EORTC-NCIC study of patients with GBM treated with RT and temozolomide was approximately 10%, and for patients with favorable prognostic factors it approached 30%.<sup>39</sup> Moreover, a patient who lived more than 20 years following the diagnosis of GBM was described, perhaps the longest documented survivor.<sup>168</sup> He had been treated with surgery and partial brain irradiation with no concurrent or maintenance chemotherapy (59 Gy of 6-MV photons in conventional fractionation delivered via a shrinking-field technique). The authors speculated that the outcome may have stemmed from the fact that he had a favorable molecular profile (e.g., methylated *MGMT* promoter, *PTEN* wild-type, and *p53* positive, which the authors termed “triple positive,” similar to the nomenclature of breast cancer). Whether this explained the long survival time is unclear. More importantly, these observations prove that one may strive to create and sustain hope for patients diagnosed with high-grade glioma.

## INTRODUCTION AND OUTLINE

Tumor Treating Fields (TTFields) is a novel antimitotic cancer treatment modality that works with specialized low-intensity (1–3 V/cm) and intermediate frequency (~200 kHz) electric fields. TTFields for glioblastoma multiforme (GBM) patients are delivered noninvasively through two orthogonal pairs of transducer arrays placed on the shaved scalp. Tumor cells are disrupted during mitosis, with the specific frequency tuned for distinct cancer cell lines, while quiescent cells are not affected.

This chapter covers a short introduction to the basics of electric fields including a description of the mechanisms of action of TTFields. Preclinical findings are outlined and the clinical application of TTFields discussed. The induced electric field distribution within the cranium is explained and illustrated with computational modeling. The last part of the chapter will comment on neuroimaging in patients treated with TTFields including a discussion of response criteria, pseudoprogression, and other treatment-related changes in patients.

## BASIC PRINCIPLES OF TTFIELDS AND PRECLINICAL FINDINGS

### Introduction to the Physics of Electric Fields

It is important to have an understanding of the physical effects of the electric fields exerted on intracellular macromolecules and proteins. These effects arise from the fact that most of these molecules have a net electric

charge (charged molecules) and/or an electric dipole moment (polar molecules). These physical properties subserve important cellular and biological functions mediated by electrical interactions between such molecules. The charged or polar molecules are also responsive to an applied electric field.

An electric field can be defined as the electric force per unit positive charge. Thus the direction of the electric field is radially outward from a positive charge (Figure 1(A)). In this field, a positive charge will move radially outwards, whereas a negative charge will move radially inwards. Molecules with net charges of opposite signs attract each other whereas molecules with net charges of the same sign repel each other. The electric field can be visualized by drawing directed curved lines (electric field lines) to indicate both the magnitude and the direction of the field. A uniform field is represented by parallel field lines (Figure 1(B)) whereas a nonuniform field is characterized by converging or diverging field lines (Figure 1(A) and (D)).<sup>1</sup> In an electrostatic field, where the source charges remain the same over time, a test charge will move toward the oppositely charged source (Figure 1(B)). In a field with time-varying or alternating source charges this charge will migrate back and forth (Figure 1(C), right). In polar molecules, the spatial separation of the positively and negatively charged poles gives rise to an electric dipole. In a uniform field, no net force is exerted on a dipole; specifically the forces acting at the ends with opposite polarity balance out and there is no movement in either direction.<sup>2</sup> Nonetheless the electric field induces a torque that rotates the dipole so it aligns with the direction of the field

**FIGURE 1** Electric field theory. (A) Opposite charges attract. (B) A constant, uniform, electric field. (C) Charges and dipoles in a time-varying, uniform electric field. (D) A dipole in a time-varying, non-uniform electric field (dielectrophoresis). From Gutin PH and Wong ET (2012) with permission.

(Figure 1(C), left). In a nonuniform field, the forces exerted on the positive and negative poles that make up the dipole are unequal, resulting in a net force and translational motion toward higher field intensity regions (Figure 1(D)). This phenomenon is termed dielectrophoresis, a function of frequency that is thoroughly described by Pohl.<sup>2,3</sup> Dielectrophoretic forces are actionable on neutral particles that are polarizable, proportional to the size of the particle, the degree of nonuniformity of the field, and the difference between dielectric properties of the particle and the suspending medium.

### Mechanisms of Action of TTFields

The effects of the application of electric fields on biological cells are an often-discussed topic within the last few decades. Analytical descriptions and theoretical investigations have led to numerous techniques for cellular characterization and manipulation, which were translated into clinical applications. Low-frequency alternating fields are employed for nerve and muscle stimulation, while high-frequency fields find medical relevance in techniques such as tissue heating or tumor ablation. The biological effects of intermediate frequency fields in the kHz region have not been extensively studied, but investigations have uncovered a number of subtle biological effects on dividing cells.

Many of the subcellular particles that are responsible for mitosis and cytokinesis are highly polar structures. Thus, particles like tubulin, actin, and DNA are very susceptible to an applied electric field. TTFields are

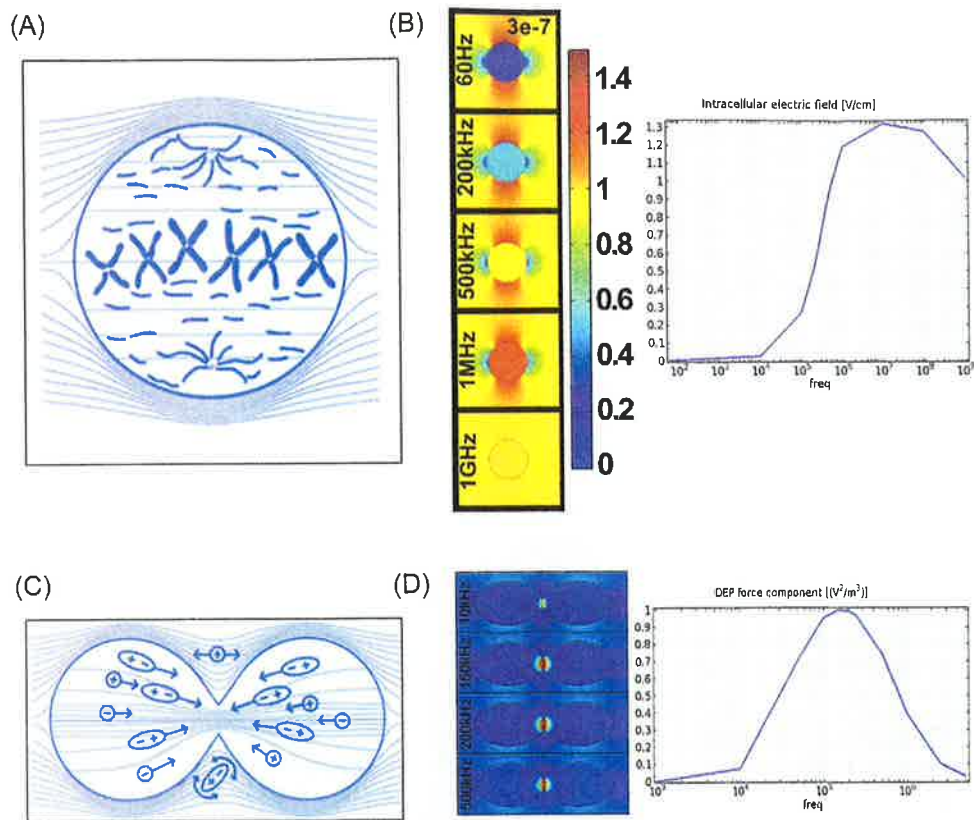

alternating electric fields of intermediate frequency (100–300 kHz) and low intensity (1–3 V/cm). The application of these fields is hypothesized to have distinct effects. For example, TTFields is believed to act by disrupting the formation of a properly functioning mitotic spindle during metaphase and by further disrupting normal cytokinesis during telophase, which leads to apoptosis. The first mechanism of action is explained by the fact that tubulin subunits align in the direction of the applied electric field, which prevents or prolongs the normal polymerization of the mitotic spindle (Figure 2(A)). The penetration of TTFields into the cell's interior was tested with computational modeling. The induced electric field distribution in and around a spherical cell exposed to TTFields during metaphase was computed using Comsol Multiphysics. The kHz frequency range marks a transition region where the intracellular field changes rapidly. For low frequencies, <10 kHz, the intracellular field is almost zero, whereas for high frequencies the impedance of the cell membrane is low and thus the cell becomes “electrically invisible” (Figure 2(B)).

The second mechanism of action results from the specific shape of the cell during anaphase and telophase. Within a dividing cell, the induced electric field is highly nonuniform with increased field intensity at the narrow furrow region. This nonuniform electric field within the cell generates dielectrophoretic forces that act on polar and charged elements in the cell, pushing them toward the cytokinetic furrow and leading to violent blebbing of the plasma membrane (Figure 2(C)).<sup>1</sup> The induced non-uniform field within the cell during different stages of cytokinesis, including the high field intensity region at the furrow, was examined by computational modeling (Figure 2(D), left). The dielectrophoretic force that is proportional to the gradient of the electric field squared was also calculated with this model. The normalized dielectrophoretic force induced in the cell during a late stage of cytokinesis was displayed as a function of frequency (Figure 2(D), right). The shape of the function predicts a very well-defined peak frequency at 150 kHz.

### Cell Biology Effects of TTFields, Preclinical Findings, and Pilot Trials

In order to test these believed mechanisms of actions, *in vitro* experiments were conducted with different cancer cell lines exposed to TTFields. First, field-induced disruptions included violent blebbing, aberrant mitotic exit, and cellular derangement consisting of incompletely or poorly divided cells that have tetraploidy, asymmetric chromosome segregation leading to aneuploidy, or slip-page into a G<sub>0</sub> state (Figure 3).<sup>4,5</sup> Second, once these cells re-enter into the next cycle of mitosis, they may trigger subsequent G<sub>1</sub> or G<sub>2</sub>/M checkpoint leading to apoptosis. Apoptotic cells were readily seen in cell cultures treated

**FIGURE 2** (A) Schematic drawing of the metaphase cell interior during TTFields treatment. Polar particles line up with the impressed field disrupting the proper formation of a functioning mitotic spindle. (B) Corresponding simulation results for the electric field distribution in and around a spherical cell exposed to TTFields of 1 V/cm. The intracellular field intensity is function of frequency. A rapid transition occurs in the kHz range, from a zero field at low frequencies to complete penetration at very high frequencies. (C) Schematic drawing of the telophase cell during TTFields treatment. The hourglass shape of the dividing cell induces a nonuniform field with high field intensities at the furrow region which induces dielectrophoretic force that pulls polarized particles toward it. (D) Corresponding simulation results for the electric field distribution in and around a dividing cell exposed to TTFields of 1 V/cm. The induced intracellular field is highly nonuniform with increased field strength at the furrow region. On the right, the normalized dielectrophoretic force induced in the cell when cytokinesis is almost complete is displayed as a function of frequency. The shape of the function predicts a very well defined peak frequency at 150 kHz. *From Novocure Inc. with permission.*

**FIGURE 3** Immunohistochemical staining of abnormal mitotic figures in TTFields-treated cultures. Malignant melanoma cultures ( $n=4$ ) were treated for 24 h at 100 kHz and then stained with monoclonal antibodies for microtubules (green), actin (red), and DNA (blue). The photomicrographs show exemplary abnormal mitoses including: polyplod prophase (A); rosette (B); ill-separated metaphase (C); multispindled metaphase (D); single-spindled metaphase (E); and asymmetric anaphase (F). *From Kirson ED, Gurovich Z, Schneiderman R, et al (2004) with permission.*

with TTFields. Lastly, the violent membrane blebbing created cytoplasmic stress resulting in the expression of calreticulin on the plasma membrane and secretion of high-mobility group protein B1 into the extracellular space which, in concert, marks the cells for immune destruction.<sup>6</sup> This type of immunogenic cell death that occurs after induction of cellular stress has also been observed after treatment with specific immunostimulating chemotherapies, like oxaliplatin and cyclophosphamide.<sup>7</sup> This is also similar to the abscopal effect from radiation, which relies on the release of intracellular tumor antigen for sensitization of the host's immune system for destruction.<sup>8</sup>

In vitro experiments and experiments in animal tumor models have shown that the efficacy of TTFields depends on the intensity, frequency, and direction of the applied electric fields.<sup>4,9</sup> The cell biology effects of alternating electric fields were tested in various tumor cell lines, including the F98 glioma cell line from the rat. The inhibitory effects of TTFields on proliferation increase with intensity. For rat glioma complete proliferation arrest was observed after a 24h exposure of a TTField intensity of 2.25 V/cm.<sup>4</sup> The optimal frequency varies among cell lines; glioma cells in tissue culture showed the strongest inhibition of cell division at a frequency of 200 kHz.<sup>9</sup> In mouse melanoma cultures, cellular damage was greatest when the applied electric field and the axis of cell division were parallel, in which case there were five times more damaged cells than live cells. This ratio was much closer to one when the angle between the electric field and the axis of cell division was close to 45° and to 90°.<sup>4</sup> Cells that were not actively dividing remained morphologically and functionally intact.<sup>4</sup> The antitumor effects of TTFields were confirmed in an intradermal mouse model for melanoma and an intracranial rat model for glioma.<sup>9</sup> In rats inoculated intracranially with glioma cells, treatment for 6 days using external electrodes to produce an electric field amplitude of 2 V/cm at 200 kHz caused a tumor volume reduction of 42.6% and 53.4% for two and three field directions, respectively, when compared with untreated tumors.<sup>9</sup>

Later, a small pilot trial of TTFields in 10 patients with recurrent glioblastoma demonstrated a median time to tumor progression of 26.1 (range 3.0–124.0) weeks, an overall survival (OS) of 62.2 (range 20.3–124.0) weeks, and a 1-year survival rate of 67.5%.<sup>9</sup> This promising outcome led to a pivotal trial which in turn resulted in the United States Food and Drug Administration (FDA) approval of TTFields as a therapy for recurrent GBM patients, as will be discussed in the next section.

The combined efficacy of TTFields and chemotherapies has been investigated. Using the IC<sub>50</sub> as a measure, there was a 1000-fold drop in the IC<sub>50</sub> of MDA-MB-231 cells when exposed to TTFields and paclitaxel in

combination, as compared to paclitaxel alone.<sup>10</sup> Similar albeit smaller drops in the IC<sub>50</sub>, 20-fold and 150-fold, were observed in the same cell line when exposed to TTFields and doxorubicin as well as TTFields and cyclophosphamide, respectively.

## CLINICAL APPLICATION OF TTFields

### Efficacy of Alternating Electric Fields Therapy for Glioblastoma

The NovoTTF-100A device was approved by the FDA in April 2011 for treating recurrent glioblastoma. The alternating electric fields are delivered by two pairs of transducer arrays positioned orthogonally onto the shaved scalp (Figure 4).<sup>11</sup> The arrays are connected to an electric field generator and a battery pack.<sup>11</sup> The recommended usage is ≥75% compliance or ≥18h daily.

In the pivotal phase III EF-11 clinical trial, the NovoTTF-100A device was demonstrated to have equivalent efficacy when compared to Best Physician's Choice chemotherapy while sparing patients the toxicities associated with systemic chemotherapies.<sup>11,12</sup> As shown in Figure 5, the respective median OS was 6.6 months for NovoTTF-100A (n=120) and 6.0 months for chemotherapy (n=117), with a hazard ratio (HR) of 0.86 (95% confidence interval (CI) 0.66–1.12; P=0.27). The respective median progression-free survival (PFS) was 2.2

**FIGURE 4** The NovoTTF-100A device. Two opposing pairs of transducer arrays are applied to the scalp and the cables are linked to the electric fields generator and a battery pack. From Novocure Inc. with permission.

and 2.1 months, with an HR of 0.81 (95% CI 0.60–1.09;  $P=0.16$ ). The PFS rate at 6 months was 21.4% (95% CI 13.5–29.3) and 15.1% (95% CI 7.8–22.3) ( $P=0.13$ ). The 1-year survival rate was 20% in the NovoTTF-100A cohort and 20% in the chemotherapy cohort. The most common toxicity associated with the NovoTTF-100A device was dermatological irritation, which occurred in 14% of patients with grade I or II severity; none of them had severe grade III or IV toxicity. Notably, the NovoTTF-100A cohort had fewer grade two or greater hematological toxicities compared with the chemotherapy cohort, 3% versus 17%, respectively, and fewer adverse gastrointestinal events, 4% versus 17%. Quality of life analysis (Figure 6) showed that patients treated with NovoTTF-100A had better cognitive and emotional function than those treated with chemotherapy. In contrast, appetite loss, constipation, diarrhea, fatigue, nausea, vomiting, and pain occurred more often in patients treated with chemotherapy than with NovoTTF-100A. Taken together, NovoTTF-100A had equivalent efficacy when compared to chemotherapy in patients with recurrent glioblastoma, while the toxicities associated with the device were mild and compared favorably to chemotherapy.

A post hoc analysis of responders and nonresponders in the EF-11 trial found that secondary glioblastomas were found in a higher frequency in responders than nonresponders in the NovoTTF-100A arm.<sup>13</sup> Additionally, all responders in the NovoTTF-100A arm had a significantly lower dexamethasone burden that statistically varied from the population as a whole, while dexamethasone had a lesser effect in the chemotherapy cohort (Figure 7).<sup>13</sup> Because dexamethasone can induce

global immunosuppression, this finding further suggests that dexamethasone not only predisposes glioblastoma patients to infections, but also likely disables their anticancer immunity.<sup>14</sup>

Mrugala et al.<sup>15</sup> published data from the Patient Registry Dataset (PRiDe) for the 457 recurrent glioblastoma patients treated with NovoTTF-100A across 91 US medical centers. Compared with the EF-11 trial, more patients in the PRiDe received NovoTTF Therapy for first recurrence (33% vs 9%) but had also received previous bevacizumab regimens (55% vs 19%). First or second recurrence (vs third or later recurrence) and no prior bevacizumab use were positive prognostic factors. They found longer median OS with NovoTTF therapy in clinical practice (9.6 months) than in the EF-11 trial (6.6 months), and greater than double the 1-year OS rate (44% vs 20%). These results suggest that NovoTTF can offer favorable clinical benefit to patients with recurrent glioblastoma, while maintaining patient tolerability and safety.

The efficacy of NovoTTF therapy for newly diagnosed glioblastoma is currently being prospectively investigated in EF-14, a randomized multicenter trial of NovoTTF therapy plus adjuvant temozolomide compared with adjuvant temozolomide alone that are administered after completion of initial involved-field cranial irradiation and concomitant daily temozolomide.<sup>16</sup> The primary endpoint is PFS and secondary endpoints include OS, PFS at 6 months, survival at 1 and 2 years, as well as quality of life assessment. All 700 subjects have been accrued and randomized in a 2:1 fashion to NovoTTF therapy plus adjuvant temozolomide:adjuvant temozolomide. The sample size has the power to

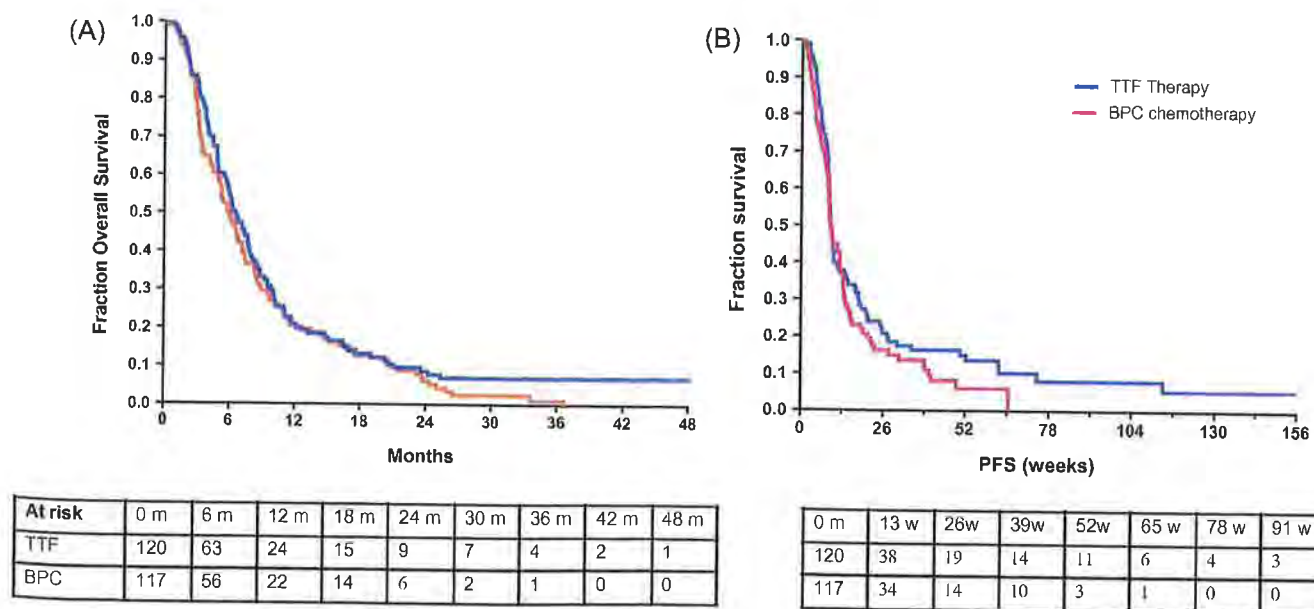

FIGURE 5 Overall survival (A) and progression-free survival (B) Kaplan–Meier curves. From Stupp R, Wong ET, Kanner AA, et al (2012) with permission.

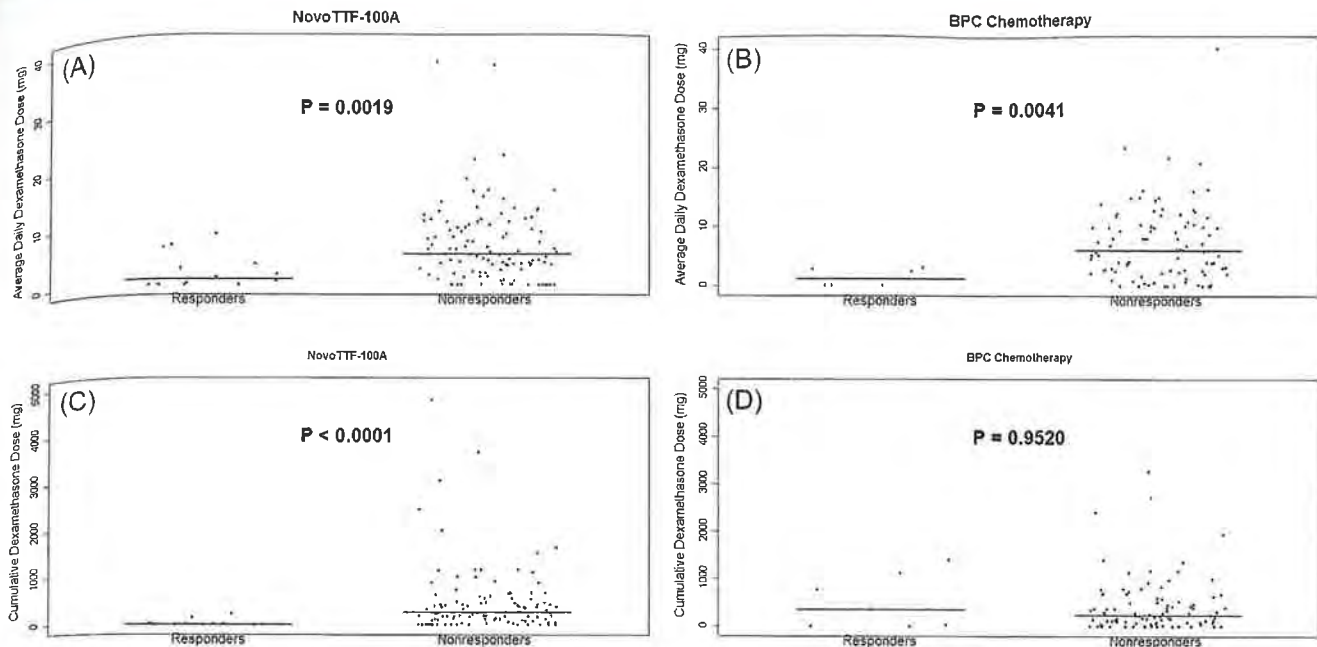

**FIGURE 6** European Organization for Research and Treatment of Cancer quality of life questionnaire (QLQ) C30 longitudinal change from baseline to 3 months. detect an HR of  $<0.78$  for PFS and  $<0.76$  for OS. The data were presented after a prespecified interim analysis of the first 315 subjects after a minimum follow up of 18 months.<sup>17</sup> In the intent-to-treat (ITT) population, there were 210 subjects randomized to the NovoTTF therapy plus adjuvant temozolomide arm and received a median of six cycles of treatment, while 105 subjects were randomized to the adjuvant temozolomide alone arm and received a median of four cycles of treatment. The per protocol (PP) population consisted of subjects that started their second cycle of treatment, or 196 in the former and 84 in the latter. Patient characteristics were balanced with respect to age, Karnofsky performance score, extent of resection, promoter methylation status of O<sup>6</sup>-methylguanine-DNA methyltransferase, and time from diagnosis to randomization. The primary endpoint analysis showed that treatment with NovoTTF therapy

plus adjuvant temozolomide was superior to adjuvant temozolomide alone, with a respective median PFS of 7.1 (95% CI 5.9–8.2) months versus 4.0 (95% CI 3.0–4.3) months (HR=0.6, log rank P=0.0014). The median OS in the former cohort, compared with the latter cohort, was also superior in both the ITT population, 19.6 (95% CI 16.5–24.1) months versus 16.6 (95% CI 13.5–19.1) months, respectively (HR=0.75, log rank P=0.034), and in the PP population, 20.5 (95% CI 16.5–24.1) months versus 15.5 (95% CI 13.5–19.1) months, respectively (HR=0.67, log rank P=0.0072). There were no unexpected adverse events. Expected grade III and IV hematological side effects (12% vs 9%), gastrointestinal disorders (5% vs 2%), and convulsions (7% vs 7%) were similar between the two cohorts. Scalp reaction was more common in the NovoTTF therapy-treated than the temozolomide-only group, 49% vs 5%, respectively, for

**FIGURE 7** Scatter plot of mean daily dexamethasone and cumulative dexamethasone dose in responders and nonresponders. (A) In the NovoTTF-100A cohort, the respective median and mean daily dexamethasone dose was 1.0 and 2.3 (95% CI 0.8–3.8) mg for responders versus 5.2 and 6.8 (95% CI 5.6–8.1) mg for nonresponders ( $P=0.0019$ ). (B) In the BPC cohort, the respective median and mean daily dexamethasone dose was 1.2 and 1.4 (95% CI 0.3–2.4) mg for responders versus 6.0 and 7.2 (95% CI 6.0–8.4) mg for nonresponders ( $P=0.0041$ ). (C) In the NovoTTF-100A cohort, the respective median and mean cumulative dexamethasone dose was 7.1 and 35.9 (95% CI N/A–72.5) mg for responders versus 261.7 and 485.6 (95% CI 347.9–623.4) mg for nonresponders ( $P<0.0001$ ). (D) In the BPC cohort, the respective median and mean cumulative dexamethasone dose was 348.5 and 525.6 (95% CI 96.5–954.7) mg for responders versus 242.3 and 431.0 (95% CI 328.1–533.8) mg for nonresponders ( $P=0.9520$ ). BPC, Best Physician's Choice; CI, confidence interval; N/A, not available.

grade I and II toxicities as well as 7% vs 5%, respectively for grade III and IV toxicities.

## ELECTRIC FIELD DISTRIBUTION WITHIN CRANIUM AND BRAIN

### Experimental Evidence

The dependence of the efficacy of TTFields on the electric field strength has been described earlier. Measurement of the applied electric field in cell cultures and in animals is straightforward. Verification of the field strength inside the human head during TTFields treatment would be desirable, but is fraught with difficulties. A single intracranial measurement has been reported in the literature, showing that an electric field intensity of 1–2 V/cm could be produced in the center of the brain by applying a potential difference of approximately 50 V between the transducer arrays.<sup>9</sup>

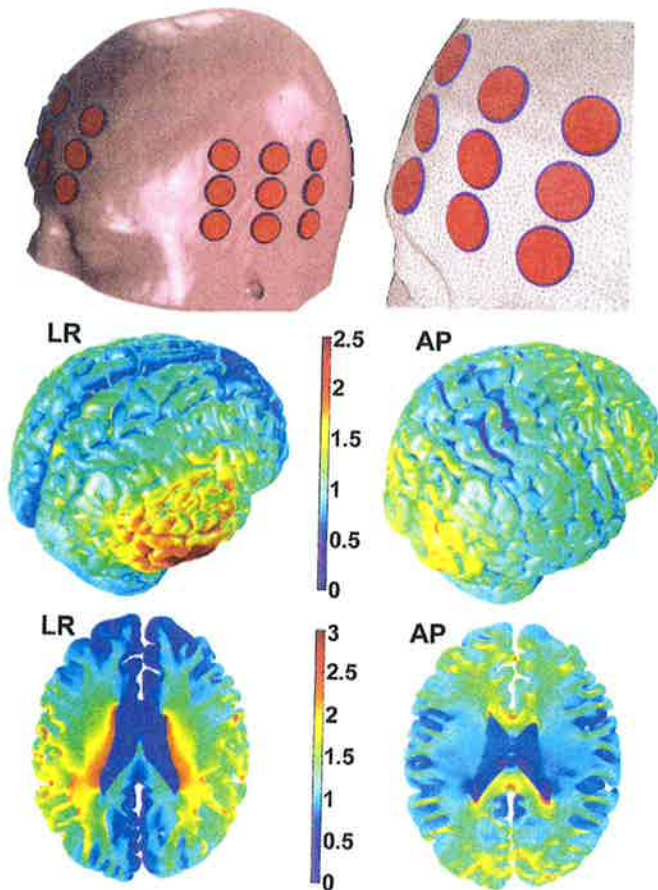

### Computational Model

Computational modeling provides a practical means to estimate the intensity of the electric field in the brain and, more generally, to examine the effect of

the shape and physical properties of the different tissues of the head on the electric field distribution. This can be achieved by combining a realistic three-dimensional representation of the head with a numerical method to calculate the electric field. The three-dimensional model is defined in terms of surfaces that correspond to the boundaries between adjacent tissues. These surfaces are represented by small triangles that make up the surface meshes (see top row of Figure 8). The bulk of the tissue is represented by small volume elements with four triangular surfaces (tetrahedra) that make up the volume meshes. The volume meshes and the surface meshes match at the boundaries. The finite element method is used to solve Maxwell's equations, based on the spatial discretization provided by the volume mesh. The numerical solution of these equations yields an estimate of the electric potential and the electric field within the head (for more details see Miranda et al.<sup>18</sup>).

The head model shown in the top row of Figure 8 was created by segmenting T1- and T2-weighted MR images of a single healthy subject.<sup>18</sup> It consists of five different tissue types: scalp, skull, cerebrospinal fluid (CSF), gray matter (GM), and white matter (WM). The ventricles were assumed to have the same properties as the CSF. Two concentric spheres were introduced

**FIGURE 8** Top row: The scalp surface with transducer arrays in red and gel layers in blue. On the right, a close-up of the anterior array also shows the triangular surface mesh elements. Middle row: The magnitude of the electric field on the cortical surface. Bottom row: The magnitude of the electric field in an axial slice at the level of the ventricles. The electric field is expressed in V/cm.

in the model to mimic the presence of a tumor with a necrotic core placed in the WM near a lateral ventricle. The necrotic core has a diameter of 1.4 cm and is surrounded by a 3 mm active shell. Four transducer arrays that faithfully reproduce those used with the NovoTTF-100A device were placed on the scalp. Each array consists of nine interconnected transducers, capacitively coupled to the scalp. The frequency of the impressed current was set to 200 kHz, and the amplitude of the current through each transducer in an active array was set to 100 mA. Transducer arrays were activated in pairs: the left-right (LR) pair and the anterior-posterior (AP) pair. In addition to the influence of the complex shape of the tissue interfaces, the intensity of the electric field also depends on the electrical properties of the tissues. The values for the electrical conductivity and permittivity used in this model were obtained from the literature (see Table 1). The electric fields were calculated using the finite element method, as described previously.<sup>19</sup> The amplitude of the potential difference

**TABLE 1** Electrical Properties of Tissues and Other Materials Used in this Study<sup>19</sup>

	Conductivity (S/m)	Relative Permittivity
Scalp	0.25	10,000
Skull	0.013	200
CSF	1.79	110
GM	0.25	3000
WM	0.12	2000
Tumor shell	0.24	2000
Tumor core	1.0	110
Gel	0.1	100
Transducer	0	10,000

applied between transducer arrays was 106 V for the AP pair and 75 V for the LR pair.

### Modeling Results

The plots in the bottom rows of Figure 8 show the magnitude of the electric field on the cortical surface and in the brain. The distribution is noticeably nonuniform, with local high electric field regions (hotspots) arising far away from the transducers. Nonetheless, in general, the electric field is highest in the regions close to the active arrays and decreases slowly as a function of distance from these arrays. The electric field exceeds 1 V/cm over large areas of the slices shown and also over a large part of the brain in the inferior-superior direction, due to the large dimensions of the arrays (about 6.2 cm by 8.4 cm). In both configurations, the magnitude of the electric field exceeded 1 V/cm in more than 60% of the total brain volume (WM+GM), and it exceeded 2 V/cm in less than 5% of the total brain volume.

The observed nonuniform field distribution is due to tissue heterogeneity. At a boundary, the component of the electric field that is perpendicular to that boundary is enhanced in the low conductivity tissue and reduced in the high conductivity tissue, giving rise to a discontinuity in the electric field intensity. This effect is particularly visible near the ventricles in the LR configuration, where part of the WM-CSF boundary is perpendicular to the applied electric field (see bottom row in Figure 8). It is also visible near WM-GM interfaces under the transducers, but the effect is less marked because the difference between the conductivities of these two tissues is not as great as at the WM-CSF interface (see AP and LR fields). Note that the electric field in the ventricles is extremely low due to the high conductivity of CSF.

The electric field in and around the tumor is also affected by tissue heterogeneity.<sup>20</sup> In this model, the presence of a high conductivity necrotic core boosts

**FIGURE 9** The magnitude of the electric field in axial (top row), coronal (middle row), and sagittal (bottom row) slices through the virtual lesion. The arrows in the axial slice indicate the direction of the alternating field. The electric field is expressed in V/cm.

the electric field in the surrounding tumor and WM (Figure 9). Again, the hotspots occur where the interfaces are perpendicular to the applied electric field. This implies that in the high electric field regions in the tumor, the field direction is always approximately perpendicular to the tissue boundaries. Also, the existence of these directional effects points to another advantage of applying the electric field in two or more directions: different directions may increase the field in different parts of the tumor. The plots in this figure also show that the electric field intensity at the tumor site is strongly influenced by the proximity to the ventricles. It is also influenced by the distance between the tumor and the active arrays, which suggests that a simple rule to place the arrays on the scalp is to minimize their distance to the tumor.

### Future Modeling Developments

The computational model used to calculate the electric field inside the head is based on classical physics and well-known numerical methods, and therefore the results are thought to be reliable. Nevertheless, there is an uncertainty in the predicted values that is due mainly

to the uncertainty in the dielectric properties of the tissues. Given the range of values reported in the literature, the uncertainty in the electric field could amount to about 50%. In the future, we plan to reduce this uncertainty in new head models by incorporating electrical conductivity data derived from diffusion tensor imaging (DTI). This is particularly important for calculating the electric fields within the tumor since the data available in the literature are scarce and so DTI data may provide better estimates of the conductivity in the necrotic core, the cancerous shell, and the edema that surrounds it. DTI does not provide information about the permittivity of the tissues, but this property has a small impact on the electric field in the frequency range of TTFields. Also, DTI data may be useful for image segmentation as it may provide a better distinction of the tumor borders and a better definition of the edema region.

### IMAGING IN PATIENTS TREATED WITH TTFields THERAPY

TTFields represents a unique treatment for glioblastoma that does not fall into the traditional categories of surgery, radiation, or chemotherapy. Compared with conventional cytotoxic therapies intended to kill tumor cells, TTFields represent a novel anticancer treatment that inhibits cell division by interfering with the formation of the mitotic spindle and by affecting polar molecules from metaphase to telophase.<sup>4,9</sup> Interpretation of imaging changes caused by treatment with TTFields therefore relies on understanding the mechanism of action and familiarity with potentially variable patterns of treatment response as well as failure. This section will discuss standard response criteria, typical imaging changes seen with conventional and investigational therapies, and early experience with TTFields.

### Response Criteria

Most clinical treatment decisions rely on changes in the size of the enhancing tumor(s): increasing size and/or number represents tumor progression and requires a change in treatment, while decreasing size and/or number represent tumor response. In 1990, in order to facilitate comparisons of treatments being tested in different clinical trials Macdonald et al.<sup>21</sup> proposed standardized response criteria that defined progressive disease (PD) as  $\geq 25\%$  increase in the size of enhancing tumor(s) (measured bidimensionally by taking the sum of the product of perpendicular diameters) or the presence of new enhancing tumor(s). Recognizing that newer treatments could induce transient increases in enhancing lesion(s) representing treatment related changes rather than tumor, the Macdonald criteria were updated in 2010 by

the Response Assessment in Neuro-Oncology (RANO) working group with several important additions.<sup>22</sup> First, an allowance was made for early treatment-related changes termed pseudoprogression. Any increase in size of enhancing lesion(s)  $\leq 3$  months after completion of radiation therapy located within the high-dose radiation field (80% isodose line) were no longer considered to represent PD, unless there was histopathologic evidence of tumor. New enhancing lesion(s) located outside the high-dose radiation field were still considered PD. After the first 3 months, RANO also defined recurrence as  $\geq 25\%$  increase of the enhancing lesions. Second, in recognition of progression of nonenhancing tumor in the setting of antiangiogenic therapy (e.g., bevacizumab), "significant" increases in T2/fluid attenuated inversion recovery (FLAIR) hyperintense signal became a new criterion for PD. This pseudoresponse, where rapid decrease in enhancing disease is not correlated with tumor response, is a well-described phenomenon with antiangiogenic therapies but unlikely to occur with treatments that do not directly affect the blood-brain barrier.

### Pseudoprogression and Other Treatment-Related Changes

Pseudoprogression is a subacute treatment induced phenomenon that presents with new and/or increasing enhancing lesion(s) that spontaneously stabilize or resolve without further therapy. Thought to represent an inflammatory response to treatment,<sup>23,24</sup> pseudoprogression is most familiar in high-grade gliomas after treatment with radiation therapy and concomitant daily temozolomide as per Stupp et al.<sup>25</sup> Similar treatment-related changes with transient imaging worsening have been described with other older therapies,<sup>26-28</sup> as well as newer therapies—notably immune modulating agents.<sup>29</sup> Wolchok et al.<sup>29</sup> described treatment response and improved survival in patients with systemic metastatic melanoma treated with ipilimumab, despite an increased burden of enhancing lesions and the presence of new enhancing lesions. They therefore proposed new immune-related response criteria to better characterize these treatment-related changes and avoid overestimations of PD, and may also be applicable after treatment with TTFields, despite the more common use of RANO criteria.

Diagnosis of treatment-related changes often requires clinical and imaging follow-up to determine stability or resolution on subsequent scans, or repeat surgery with histopathologic confirmation of necrosis without tumor. Accurate determination of treatment-related changes versus tumor is necessary, because the two involve antithetical management. Treatment-related changes may require steroids or other therapy for relief of symptomatic edema and/or mass effect, or in unrelenting cases of

radiation necrosis may also necessitate surgery or antiangiogenic therapy.<sup>30-32</sup> Patients should in many cases continue their current, probably effective therapy. In contrast, recurrent tumor requires discontinuation of current ineffective therapy and consideration of new therapy.

### Advanced Imaging Techniques

The changes in size used by most response criteria to determine treatment response may occasionally lag behind alterations in tumor biology, where effective therapy may decrease metabolically active tumor that remains stable in size. In other situations, changes in size may be misleading when accelerated cell killing, treatment-related inflammatory changes, and blood-brain barrier disruption—as occurs with pseudoprogression—may induce an increase in enhancing lesions and edema to mimic worsening tumor. To complement traditional magnetic resonance imaging (MRI) sequences, advanced imaging techniques enable measurement of biological changes that do not depend upon changes in size. These technologies interrogate different aspects of tumor pathophysiology and may provide independent predictors of patient outcome, confirmation of suspected progression or treatment effects in clinical trials, as well as measurement of biological effects of investigational drugs. Popular techniques that are briefly discussed below include MR perfusion, MR spectroscopy, and positron emission tomography (PET).

Dynamic contrast enhanced (DCE) T1, dynamic susceptibility contrast T2\*, and arterial spin labeling perfusion MR techniques provide information about tumor microvasculature, neoangiogenesis, and blood-brain barrier disruption. Multiple studies have shown utility in differentiating between recurrent tumor and radiation injury, including pseudoprogression. For example, while both recurrent tumor and radiation injury can show increases in size of enhancing and T2/FLAIR lesions, an increase in the relative cerebral blood volume, as measured by MR perfusion, is seen with recurrent tumors but not in radiation necrosis.<sup>24,33-35</sup> Increases in perfusion in the setting of tumor progression are related to increased microscopic vessel density from tumor neoangiogenesis. The enhancing lesions of radiation injury instead reflect increased leakiness with inflammatory mediators and blood-brain barrier disruption.

MR spectroscopy provides the semiquantification of metabolites that can characterize the composition of a lesion in the brain. This can aid in the diagnosis of radiation injury, which typically demonstrates low choline (a cell membrane marker) and possibly high lipid/lactate peaks (indicating necrosis). In contrast, tumors typically demonstrate high choline and low *N*-acetylaspartate (NAA), which may also be expressed as a choline/NAA ratio.<sup>36,37</sup>

PET uses metabolic tracers (most commonly, the glucose analogue 2-deoxy-2-( $^{18}\text{F}$ )fluoro-D-glucose (FDG)) to study brain lesion metabolism. FDG is preferentially taken up by hypermetabolic tumor cells, and not by radiation injury. Although studies have suggested accuracy for distinguishing tumor recurrence from radiation changes, the high basal uptake of FDG in the brain that results in high background signal continues to represent a technical challenge.<sup>38-40</sup> Other nonFDG PET agents may prove to be more sensitive and specific to treatment changes, but these are still being investigated in clinical trials and not widely available.

### Imaging in Patients Treated with NovoTTF Therapy: Early Experience

The unique mechanisms of action of TTFields and its effects on tumor biology present additional challenges to traditional response criteria based on changes in the size of the enhancing tumor. The electric fields interfere with the organized coalescence of the mitotic spindle and affects polar molecules from metaphase to telophase to prevent cell division at the  $G_1$  or  $G_2/M$  checkpoints. As cells are required to be in active mitosis, any immune-mediated apoptosis induced by treatment may therefore be expected to require some time to occur.

Some patients may have a delay in radiographic response after treatment with TTFields. In a post hoc analysis of pilot and phase III trial data, Vymazal and Wong<sup>41</sup> reported that the median time to response was delayed by 5.2 months. This delay suggests that the relatively slow TTFields induced tumor cell death may be insufficient in symptomatic patients with rapidly progressive tumors. This is despite the fact that tumor cells with active mitoses are most susceptible to the electrical fields. While delayed, the response may be durable with a median response duration of 12.9 months.<sup>41</sup>

Some patients may also demonstrate transient increases in enhancing lesion size that do not represent tumor growth (Figure 10). This is similar to the pseudoprogression that is most familiar after standard radiation therapy and temozolomide chemotherapy. In these delayed responders with initial tumor growth, the median time to reversal of tumor growth was 4 months (95% CI, 2.3–7.4).<sup>41</sup> Villano et al.<sup>42</sup> described a patient who survived greater than 6 years using TTFields as monotherapy, where initial growth of the enhancing recurrent glioblastoma was followed by slow decrease. These observations are consistent with kinetic model stimulations in which tumor growth is maximum at 1 month followed by a reduction of tumor volume to 35% near 6.8 months, which is equivalent to a 50% decrease or partial response in bidimensional tumor measurement according to Macdonald or RANO criteria.<sup>41</sup>

Given the possibility for delayed treatment response, caution should be applied when interpreting worsening imaging results in patients treated with TTFields. New enhancing lesions within the treatment field should be considered possible tumor progression or treatment-related change (e.g., pseudoprogression), and investigated using additional or advanced imaging to confirm the diagnosis. Confirmation should be sought using advanced imaging, with the choice of MR perfusion, spectroscopy, PET/computed tomography (CT) or other techniques depending on the local expertise and available technology. New enhancing lesions outside the treatment field, however, should be considered tumor progression as per the RANO criteria.

Another consideration in evaluating response in patients treated with TTFields pertains to the treatment fields themselves. Treatment fields are nonuniform and different parts of the brain may receive different “doses” based on field strength and positioning.<sup>19</sup> Tumor progression may occur more frequently at the edges of the treatment fields due to lowered field strengths at the periphery.<sup>20</sup> It is important to recognize that treatment design, field strength, and cell size may all play a role in out-of-field recurrences. If recurrence occurs, new enhancing tumors outside of the tumor treatment field may be treated by adjusting the treatment field maps using the NovoTAL software.

## CONCLUSIONS

Alternating electric fields represent a novel treatment strategy for patients with recurrent glioblastoma, and a viable alternative to conventional chemotherapies. This is because these fields interfere with tumor cell division at a different part of the cell cycle, rendering it unique to other oncolytic agents. In vitro, TTFields can be combined with specific chemotherapies to achieve at least an additive anticancer effect. The modeling study clearly demonstrates the need for patient-specific head models in order to predict the electric field as accurately as possible. Such models could be used in a retrospective study to establish the link between the electric field distribution and treatment outcome, both positive and negative. They could also be used prospectively for treatment planning. In this case, the positions of the transducer arrays and the current delivered through each pair could be used a priori to optimize the electric fields delivered to the tumor could be determined a priori. Typical optimization criteria would include high intensity and uniformity of the electric field in the area containing tumor and edema, as well as low field intensity in the surrounding brain tissues.<sup>43,44</sup>

Early clinical experience has demonstrated that the NovoTTF therapy-induced cell death may in some

**FIGURE 10** Patient with glioblastoma 18 months after completion of radiation therapy and temozolomide followed by adjuvant temozolomide, with bevacizumab added 5 months earlier for recurrent tumor. Axial FLAIR (A) and contrast T1-weighted (B) images demonstrate nonenhancing hyperintense and enhancing disease, respectively, indicating failure of treatment. The bevacizumab was discontinued and the patient began CPT-11 and NovoTTF-100A. Two months later, there is decreased nonenhancing (C) and enhancing (D) disease. DCE MRI perfusion shows no leakiness on the Ktrans map (E) or hyperperfusion on the plasma volume map (F) multivoxel MRI spectroscopy (G) demonstrates a lipid/lactate peak with decreased remaining metabolites, and FDG PET/CT (H) confirms absence of hypermetabolic activity. These are all consistent with absence of active high-grade tumor. CPT-11 was discontinued 17 months later due to fatigue and excessive number of cycles, while NovoTTF-100A was continued as monotherapy for another 5 months before another progression (not shown). BCNU (bis-chloroethylnitrosourea) was added to the treatment regimen for the patient who survived another 2 years.

patients result in a delayed treatment response or transient worsening before response. Since it may be unclear whether this worsening detected by conventional MRI is due to tumor progression or evolving

treatment-related changes, advanced imaging techniques, and follow up should be performed to confirm the diagnosis whenever possible. Future experience will help determine the rate and time frame of these

treatment-related changes, and the optimal imaging strategy to diagnose treatment response or tumor progression.

## Introduction

There have been numerous exciting advances in cancer care, and specifically to the field of neuro-oncology. Basic science research has dramatically increased the understanding of tumor biology, and better defined the role of cancer stem cells in maintaining tumor growth and resistance to therapy. The result of this work has been the identification of numerous potential targets for therapy, making neuro-oncology a prime area for translational research. Clinically, a coordinated team approach among surgical, medical, neuroimaging, and radiation oncology and pathology ensures a timely and accurate diagnosis, and that the most up-to-date and effective treatment options are available to the patient for their specific cancer. This chapter reviews some of the promising areas in diagnostic testing, neuroimaging, and therapies that are impacting the understanding of brain tumors and brain tumor care.

## Background/Epidemiology

### Metastasis

The most common malignant intracranial tumors are metastases, which spread hematogenously from systemic solid tumors or hematologic malignancies (Fig. 22.1a, b). Less frequently, systemic cancer may spread to the central nervous system (CNS) as dural (Fig. 22.2) or leptomeningeal metastasis (Fig. 22.3a, b). CNS metastases are often a manifestation of advanced and progressive systemic cancer, but rarely may be the presenting feature of an occult malignancy. The likelihood of developing brain metastasis varies greatly depending on the primary cancer site. Individuals with lung cancer develop brain metastasis at an estimated incidence of 19.9 %, breast cancer 5.1 %, and GU malignancies 1 % or less [1].

Brain metastases characteristically present with focal neurologic dysfunction related to the site of involvement, or progressively worsening headache. Typical radiographic features are a peripherally enhancing lesion or lesions occurring at the cortical/subcortical junction. Posterior fossa lesions, cystic lesions, and tumors with an imaging appearance similar to primary brain tumors may also occur. Headache, confusion/depressed level of consciousness, and cranial neuropathies are the most common presenting signs and symptoms of meningeal carcinomatosis, with
